it should be sent for culture and sensitivity and the patient treated appropriately for the infection.

## Metatarsal Joint

### Indications

This injection procedure is used to diagnose and treat Morton's metatarsalgia and Morton's neuroma.

### Techniques

After informed consent is obtained, the patient is positioned for optimal access to the dorsal aspect of the foot. The metatarsal joint interspaces are palpated for swelling and tenderness. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1-in. (2-cm), 25-gauge needle is inserted at the point of maximal tenderness, perpendicular to the skin, and advanced about 1 cm. After negative aspiration, a 2-mL mixture of 5 mg of triamcinolone acetonide (or equivalent) and local anesthetic is injected (Fig. 67-59).

### Comments

Morton's metatarsalgia often involves the first and second interdigital spaces. Morton's neuroma is neuritis of the plantar digital nerves located between the third and fourth metatarsal heads and occasionally in the nerve between the second

and third metatarsal heads. This procedure is used to treat postoperative scar pain often present after surgical removal of a Morton's neuroma.

### Complications

Serious complications are uncommon with appropriate needle placement.

## CONCLUSION

The injection procedures outlined in this chapter are appropriately used in conjunction with other aspects of rehabilitation to reduce pain and increase function. Sterile technique and knowledge of anatomic relationships are required.

Aspiration is performed before injecting and is repeated as necessary throughout administration of medication to prevent intravascular injection. For optimal results and safety with injection techniques, the practitioner needs the necessary skill, training, and education to perform the procedures. Haste and failure to observe the necessary precautions by the practitioner increase the risks for any procedure. Knowledge of the anatomy pertaining to each injection procedure is a requirement for safe and successful outcomes in even the simplest injection.

# Spinal Injection Procedures

Spinal pain, especially low back pain (5% incidence and 60% to 80% lifetime prevalence in the United States), is very common (1). Low back pain is the leading cause of disability in people younger than 45 years. Although spinal pain often improves and resolves, a significant proportion of patients have ongoing symptoms and pain recurrence. Low back pain is a costly disorder with an annual cost approaching \$50 billion (1). Therefore, a comprehensive rehabilitation approach that improves outcomes for patients with spinal pain can have a significant positive medical and economic impact. Adequate pain control can minimize disability, maximize function, improve quality of life, and potentially improve long-term outcomes by preventing the development of chronic pain syndromes. Spinal injection procedures have become an integral part of comprehensive rehabilitative management for individuals with spinal pain. Judicious use of these interventional procedures on carefully selected patients can provide optimal pain control, reduce disability, and improve functional outcome. This chapter is intended to discuss common spinal interventional procedures in an evidence-based manner and provide some instruction on performance of these procedures.

## EPIDURAL STEROID INJECTION

Epidural steroid injections (ESIs) for the management of lumbar radicular pain provide the advantage of delivering potent anti-inflammatory agents in a localized fashion to the area of affected nerve roots, thereby decreasing the systemic side effects often seen with orally administered steroids. Lumbar ESIs have been endorsed by the North American Spine Society (2) and the Agency for Health Care Policy and Research (3) as an integral part of nonsurgical management of radicular pain from lumbar spine disorders. Cervical and thoracic ESIs are also being used to treat cervical and thoracic radicular pain respectively, but have not, as of the time of this writing, received similar endorsement.

## Pathophysiology of Radicular Spinal Pain

Radicular pain is the result of nerve root irritation or inflammation (4–13). It is often described as a sharp, lancinating, and cramping discomfort that may feel like it is “shooting” from the spine along a dermatomal distribution. Other clinical manifestations of nerve root inflammation may include dermatomal hypesthesia or hyperalgesia, weakness of muscle

groups innervated by the involved nerve roots, diminished deep tendon reflexes, and positive neural tension signs such as the straight-leg-raising test or Spurling’s maneuver.

Animal research in rats has revealed severe local inflammation in the epidural space and nerve root after injection of autologous nuclear material into the epidural space (6). High levels of PLA2, an enzyme that regulates the initial inflammatory cascade, have been demonstrated in herniated disc material from surgical samples in humans. Leukotriene B<sub>4</sub>, thromboxane B<sub>2</sub>, and inflammatory products also have been discovered within herniated human discs after surgery (4). Animal models have demonstrated that injection of PLA2 into the epidural space induces local demyelination of nerve roots and subsequent ectopic nerve discharges, which is considered to be the primary pathophysiologic mechanism of radicular pain (5). Interleukin 1 and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) have been detected in the herniated nucleus pulposus and found to play an important role in the pathogenesis of radicular pain from a herniated nucleus pulposus (11,12,14,14a).

Radicular low back pain caused by spinal stenosis probably occurs through the impedance of normal nerve root vascular flow and subsequent development of nerve root malnutrition, nerve root edema, and nerve root dysfunction (13). Chronic nerve root compression can induce axonal ischemia, impede venous return, promote extravasation of plasma proteins, and cause local inflammation (7). Venous congestion and arterial compromise can induce radiculopathy.

In a rat study, the compression of dorsal root ganglion (DRG) resulted in the reduction in K<sup>+</sup>, a hyperpolarizing shift in TTX-S Na<sup>+</sup> current activation, and an enhanced TTX-R Na<sup>+</sup> current. These phenomena may all contribute to the enhanced neuronal excitability and thus to the pain and hyperalgesia associated with the compression of DRG. In a separate study, an inflammatory soup (IS) consisting of bradykinin, serotonin, prostaglandin E<sub>2</sub>, and histamine (each 10<sup>-6</sup> M) was applied topically to the DRG that had undergone chronic compression. IS remarkably increased the discharge rates of somata of a chronically compressed dorsal root ganglion (CCD) in rat neurons and evoked discharges in more silent-CCD than control neurons. Inflammatory mediators, by increasing the excitability of DRG somata, may contribute to chronic compression-induced neuronal hyperexcitability and to hyperalgesia and tactile allodynia (15). That these findings of lumbar radicular pain may be associated with increased excitability of involved DRG neurons was confirmed by a similar animal study (16).

In summary, clinical practice and animal research suggest that radicular spinal pain is the result of nerve root inflammation in the epidural space that is provoked by leakage of disc material, compression of the nerve root, and/or irritation of DRG from spinal stenosis. In addition, the pain may also relate to the enhanced neuronal excitability of the DRGs associated with chronic compression that occurs in neuroforaminal stenosis due to spondylosis or nucleus pulposus herniation.

Because radicular pain appears to originate from inflammation within the epidural space and nerve root, analgesic effects of epidural corticosteroids most likely are related to their anti-inflammatory effect. Underlying corticosteroid anti-inflammatory mechanisms include inhibition of phospholipase A<sub>2</sub> and inflammation (14, 14a), inhibition of neural transmission in nociceptive C fibers (5), reduction of capillary permeability, and nonselective inhibition of TNF- $\alpha$  (12) and IL-1 (17).

### Rationale for Epidural Injection of Corticosteroids and Local Anesthetics

Given the fact that the efficacy of corticosteroids apparently depends on their anti-inflammatory mechanism, it stands to reason that epidural injection should have higher efficacy in reducing nociceptive-induced radicular pain if applied earlier in the inflammatory process. In contrast, at least some of the nerve root fibers undergo fibrosis and necrosis in chronic radicular pain states. This perhaps explains in part why corticosteroid injections are less beneficial in the chronic setting. In fact, one study demonstrated little efficacy of cervical ESIs in atraumatic (i.e., stretched or compressed nerve roots) neuropathic radicular pain (68). In addition to timing of administration, the actual route of administration is important in treating radicular pain. For example, one study found that corticosteroid administration through the intravenous approach only offered short-term (<3 days) benefit (18). However, an open trial without control patients showed that intravenous methylprednisolone resulted in improvement in all 11 patients at the median follow-up time of 3.8 months (19). At the time of this writing, there have been only a couple case reports and no peer-reviewed, randomized controlled studies on the benefit of oral steroids in the treatment of radiculopathy. Some case reports provide initial data (20,21).

Local anesthetics are often administered along with corticosteroids during epidural injections. By blocking sodium channels, local anesthetics impair peripheral neurotransmission of pain impulses, normalize the hyperalgesic state of the nervous system, and prevent and/or reduce the neuronal plasticity in the central nervous system by reducing the peripheral nociceptive input. Perhaps this, in part, explains the well-recognized phenomenon in clinical practice of pain relief after injection of local anesthetic often outlasting the physiological action of the anesthetics. In chronic (>6 months in duration) radiculopathy, neuropathic pain likely plays a greater role than pain due to inflammation. Since local anesthetics act directly on axons rather than acting as anti-inflammatory agents like

corticosteroids, one would anticipate that they have efficacy in chronic radiculopathy. In fact, one study demonstrated the important role of local anesthetics in reducing chronic cervical radicular pain and discussed their possible mechanism via the neuronal plasticity that has been proposed to play a role in chronic radiculopathy (22).

### Indications for ESIs

The primary indication for ESIs is radicular pain associated with a herniated nucleus pulposus or spinal stenosis. A variety of other indications have been reported with variable results (23,25–29). These include radicular pain associated with lumbar spine compression fracture, facet or nerve root cysts, postlaminectomy back pain, cervical strain syndromes with associated myofascial pain, and postherpetic neuralgia (23,25–29).

### Contraindications for ESIs

Contraindications for epidural corticosteroid injections include systemic infection, local infection at the site of planned injection, bleeding disorder or full anticoagulation, history of significant allergic reactions to the components of the solution for injection, severe central canal stenosis at the level of planned injection, and lumbar ESI in pregnant women (23,25–29). Caution should be used when performing injections in patients with poorly controlled diabetes and in individuals who have a history of severe or uncontrolled hypertension or congestive heart failure (CHF), because of the potential for steroid-induced fluid retention.

### Techniques

Cervical, thoracic, and lumbar epidural injections may be performed through either interlaminar or transforaminal approaches, and lumbosacral injections may also be performed through the caudal route (23,25–29).

## INTERLAMINAR EPIDURAL INJECTION

### Technique

The patient is placed in a prone position, ideally with a pillow or abdominal roll under the abdomen to help open up the lumbar interlaminar space by reversing the lumbar lordosis. The skin is then prepped and draped in a sterile manner. The targeted interlaminar space is identified using an anteroposterior (AP) fluoroscopic view, the vertebral body endplates at the targeted level are “squared off” by adjusting the relative cephalad-caudad orientation of the fluoroscope, and the fluoroscope position is further adjusted so that the proposed needle entry site into the epidural space is centered with respect to the fluoroscopic view in order to reduce parallax error. After the local skin and underlying tissues are anesthetized with 1% lidocaine, a 17- or 20-gauge epidural needle (e.g., Tuohy or Crawford) of appropriate length, depending upon body habitus, is inserted at the injection site. The epidural needle then penetrates the skin, subcutaneous tissue,

paraspinal muscles (paramedian approach) or the interspinous ligament (midline approach), and ligamentum flavum, where increased resistance is usually felt. At this point, the needle stylet is removed and the epidural needle is connected, ideally via extension tubing, to a Luer-Lok low friction glass or plastic syringe filled with about 2 mL of preservative-free saline. (Although the syringe can alternatively be filled with air, this can theoretically lead to an air embolus with inadvertent intrathecal injection and is believed to cause a higher incidence of postepidural headaches.) As the operator's one hand advances the needle slowly into the ligamentum flavum, the other hand exerts steady gentle pressure on the plunger of the syringe. Depending upon the experience of the injectionist and the patient's body habitus, the entire procedure can either be done using an AP view, or additional lateral views can also be obtained to help judge the depth of penetration. Once the needle penetrates the ligamentum flavum, loss of resistance should be detected by the hand holding the Luer-Lok syringe because saline will be suddenly injected owing to the negative pressure within the epidural space. Aspiration is then performed to ensure no CSF or blood return. (If blood is present, the needle position should be readjusted until no blood return is found. If CSF return is present, the needle is either withdrawn and the procedure attempted at an adjacent level or a caudal or transforaminal approach considered for the epidural.) A small amount of contrast (usually in the range of up to several milliliters) is then injected to visualize an epidurogram pattern that can be described as a Christmas tree, a bunch of grapes, or a vacuolated pattern (Fig. 68-1). Two other contrast patterns are possible if there has been false loss of resistance (in which the needle has not yet penetrated into the epidural space) or accidental needle penetration through the subarachnoid membrane. In these cases, contrast

pattern recognition is essential. For example, in situations of false loss of resistance, the injected contrast typically appears as a local accumulation of contrast, whereas a typical myelogram revealing a relatively tubular (column-shaped) contrast pattern is generated when there has been subarachnoid membrane penetration. In the latter situation, the needle should be withdrawn, and the injection can be reattempted at an adjacent interlaminar space or by switching to a caudal or transforaminal approach. Once the needle is confirmed in the epidural space and no vascular pattern is observed upon contrast injection, a mixture of 4 to 10 mL of solution containing 80 to 125 mg of preservative-free methylprednisolone or 12 mg of preservative-free betamethasone sodium phosphate (Celestone Soluspan) and preservative-free 1% lidocaine with or without saline is injected into the epidural space through the epidural needle.

Several procedural modifications are recommended for cervical or thoracic interlaminar epidural injections due to the presence of the underlying spinal cord. For example, the cervical or thoracic interlaminar epidural injections should not be performed at the level of herniated nucleus pulposus or spinal stenosis, to avoid further potential spinal canal compromise and spinal cord compression. Furthermore, consideration should be given to directing the needle so that it contacts the inferior aspect of the lamina, to provide a clearly felt sense of depth prior to engaging the ligamentum flavum. The needle is then withdrawn slightly and directed into the ligamentum flavum. Further needle advancement should be performed using a lateral view and in addition to using the loss-of-resistance technique, the needle tip should not be advanced further than the laminar line to avoid the potential penetration of the dura mater or spinal cord injury. Epidural dye pattern recognition should be performed after a minimal amount of contrast has been injected since a total volume of less than 4 mL is recommended in these body regions (Figs. 68-2 and 68-3).

**FIGURE 68-1.** Lumbar interlaminar epidural injection. AP view showing a typical vacuolated epidurogram.

**FIGURE 68-2.** AP view of cervical interlaminar epidural injection demonstrating typical "honeycomb" pattern of epidurogram.

**FIGURE 68-3.** AP view of thoracic interlaminar epidural injection at the T10-11 level. Note the angle of the needle relative to the axis of the spine.

## TRANSFORAMINAL EPIDURAL INJECTION

### Comment

In one systematic review comparing transforaminal, interlaminar, and caudal ESIs, the authors concluded that there was moderate evidence for long-term (>6 weeks) relief of lumbar radicular pain using the transforaminal and caudal approaches, but limited evidence using the interlaminar approach (30). The authors also concluded that there was moderate evidence for relief of cervical nerve root pain using both the transforaminal and interlaminar approaches (30). Another study concluded that the transforaminal approach was more effective than the interlaminar or caudal approaches in treating lumbar pain (31). A review showed transforaminal lumbar ESIs under fluoroscopic guidance to be more cost effective than blind interlaminar and caudal ESIs (32).

As of this writing, no peer-reviewed, randomized controlled studies have compared transforaminal and interlaminar ESIs in the thoracic region.

### Technique

For lumbar transforaminal epidural injection (TEI), the patient is placed in a prone position with a pillow or abdominal roll under the abdomen to at least reduce and ideally reverse the lumbar lordosis in order to open up the foramen. Using an ipsilateral oblique fluoroscopic view, the x-ray tube (source) of the C-arm fluoroscope is generally angulated in either a caudal direction (for L5-S1 and L4-5 TEI) or cephalic direction (for L3-4 and above TEI) to square the inferior endplate of the vertebral body, and to place the superior articular process of the subjacent segment pointing at 6 o'clock of the pedicle of the above level that appears as a Scottie dog eye. Local skin is then prepped and draped in a sterile manner. A local skin wheel is raised with 1% lidocaine at the needle entry site and the subcutaneous tissue in the needle trajectory path is

infiltrated with 1% lidocaine. A 22- or 25-gauge spinal needle of appropriate length is inserted and directed down and parallel to the fluoroscopic beam toward the “safe triangle.” The safe triangle is formed by the lower border of the pedicle, the lateral margin of the vertebral body, and the traversing nerve root. To avoid deep needle placement and potential injury to the vasculature or nerve root or DRG in the neuroforamen, the novice injectionist should advance the needle until the needle tip touches the lower edge of the Scottie dog eye, the junction of the transverse process and the superior articular process. The needle is then slightly withdrawn for 2 to 3 mm and redirected inferiorly just under the lower edge of the transverse process for about 0.5 mm. Further advancement of the needle should be under AP and cross table (lateral) views. The final needle tip position should be at the posterior half of the neuroforamen just under the pedicle in the lateral view to minimize the potential injury to the vasculature, nerve root, or DRG. In the AP view, the needle tip should not be medial to the medial edge of the pedicle to avoid penetrating the dura mater. For S1 transforaminal injections, the eye of the Scottie dog can also be used as an injection landmark. Using a slightly caudad and ipsilateral fluoroscopic view, the S1 Scottie dog image is outlined. The needle should be directed to the outer upper quadrant of the neuroforamen. In the lateral view, the needle tip should not pass the anterior margin of the sacral canal that appears as a radiological lucent strip. A neurogram pattern should then be visualized under an AP view (Fig. 68-4).

For the L5-S1 foramen, the C-arm source often needs to be tilted in a caudad direction to accommodate any remaining lumbar lordosis. An ipsilateral oblique projection is then used to visualize the Scottie dog and the target is identified as the

**FIGURE 68-4.** Left L5-S1 TEI. AP view showing a neurogram pattern of left S1 and L5 nerve roots.

**FIGURE 68-5.** L5-S1 and S1 TEI. Oblique view showing needle just under the 6 o'clock position of the L5 pedicle and outer lateral quadrant of S1 for L5 and S1 TEIs respectively.

region immediately under the pedicle, slightly lateral to the 6 o'clock position (Fig. 68-5). This position leads to needle placement in the neuroforamen, ventral to the nerve root. Lateral imaging is used to demonstrate the needle depth, which should be located at the superior portion of the intervertebral foramen, just under the pedicle (Fig. 68-6). An AP view is then obtained to ensure that the needle tip is located at the "safe triangle," slightly lateral to the 6 o'clock position of the pedicle. The safe triangle is formed by the lower border of the pedicle, the lateral margin of the vertebral body, and the traversing nerve root. A needle position located within the safe triangle and lateral to the 6 o'clock position is deemed safe because it will not penetrate the nerve, blood vessels, or dura mater. Nevertheless, because of the precarious location of the nerve root and the DRG, caution should be exercised by advancing the needle slowly upon entering the neuroforamen, to avoid needle penetration of these neurologic structures. If the patient complains of radicular pain or paresthesias, the needle should be withdrawn and redirected superiorly. Once the needle is deemed at the proper position, approximately 1.0 mL of the contrast is injected under live fluoroscopic view. The needle should be redirected if there is vascular uptake of the contrast. The injected contrast should ideally outline the nerve root and also show epidural spread. Three milliliters of a mixture of solution containing 40 to 125 mg of preservative-free methylprednisolone, 6 to 9 mg of preservative-free betamethasone sodium phosphate, 40 to 50 preservative-free triamcinolone (33,34), or other equivalent dose of preservative-free corticosteroid and preservative-free 1% lidocaine can be slowly injected into the neuroforamen through the spinal needle (25,26).

A thoracic TEI is performed with the patient in a prone position. The fluoroscope should be directed in a similar

**FIGURE 68-6.** Lumbar L5-S1 and S1 TEIs. Lateral view demonstrating contrast in the ventral epidural space. Theoretically, the transforaminal approach should achieve more anterior flow of the injectate than would be typical for an interlaminar approach.

fashion as for lumbar TEI. A critical part of the injection is the correct identification of a clear rectangular-shaped clear space window under the fluoroscope. The upper and lower borders of the rectangle are the lower edge of the lamina of the same vertebral segment and the upper edge of the inferior vertebral endplate of the same segment. The lateral and medial borders of the rectangle are the medial edge of the rib head and the pars interarticularis of the same segment, respectively. After proper skin preparation and local anesthesia, the spinal needle is inserted and directed toward the lower edge of the Scottie dog eye using the same technique as in the lumbar TEI. Caution should be exercised not to direct the needle outside the clear rectangle window. If the needle strays too far laterally outside the rectangular window, it can penetrate the pleura, resulting in a pneumothorax. Needle placement too medially outside the rectangular window can result in spinal cord injury. The final needle position should be in the posterior half of the neuroforamen in the lateral view and the 6 o'clock position of the pedicle in an AP view. The contrast and corticosteroid are injected in a similar fashion as when performing a lumbar TEI.

A cervical TEI is performed, with the patient in a supine position and the head turned to the contralateral side. A peripheral intravenous line should be placed, and vital signs, as well as oxygen saturation, should be monitored. The C-arm fluoroscope is rotated ipsilaterally and angulated either cephalically or caudally to maximally visualize the targeted neuroforamen (Fig. 68-7). After aseptic skin preparation and draping, the skin entry site is anesthetized with 1% lidocaine. A 22- or 25-gauge, 3.5-in. spinal needle is then inserted at the injection site and directed down and parallel to the fluoroscopy beam until the needle contacts the superior articular process forming the

**FIGURE 68-7.** Oblique view of transforaminal cervical epidural injections showing needles in the posterior walls of the C4/5 and C5/6 neuroforamina.

posterior wall of the neuroforamen. At this point, the needle tip is withdrawn and directed slightly anteriorly to “walk off” the superior articular process and slip into the neuroforamen. The C-arm is turned to the AP view to assess the needle depth. The needle should be advanced in millimeter-by-millimeter increments in the AP view to ensure that the needle is not advanced past the center of the lateral mass (Fig. 68-8). Overzealous advancement of the needle into the inner half of the lateral mass can potentially lead to penetration of the dura

**FIGURE 68-8.** AP view of transforaminal cervical epidural injection demonstrating left C6 neurogram.

into the subarachnoid space or into the spinal cord. The desired final needle location is the posterior wall of the targeted neuroforamen in the oblique view and the lateral half of the lateral mass in the AP view. After negative aspiration of the cerebrospinal fluid (CSF) or blood, 0.5 to 1 mL of contrast is injected under real-time imaging to exclude a vascular pattern. The needle should be repositioned if there is either blood flashback in the needle hub or a vascular pattern upon contrast injection. If the patient complains of paresthesias or radicular pain, the needle also needs to be repositioned. With satisfactory needle position, the injected nonionic water soluble contrast often outlines the exiting spinal nerve and fills the neuroforamen with epidural spreading or an epidurogram. After the satisfactory position, 1.0 mL of a test dose of 1% lidocaine is injected, and the patient is monitored for 2 minutes for any changes in vital signs or consciousness or neurological deficits in the extremities that would indicate an intravascular injection. For patients without abnormal signs, 40 mg of methylprednisolone, 6 mg of betamethasone sodium phosphate, or 10.25 mg of nonparticulate dexamethasone in a total volume of less than 2 mL per neuroforamen may then be injected (25,26,35). To prevent inadvertent arterial embolism into the spinal cord and brain stem, a nonparticulate soluble corticosteroid such as dexamethasone is recommended for cervical transforaminal ESI.

## CAUDAL LUMBAR EPIDURAL INJECTIONS

Caudal lumbar epidural injections are performed by inserting a needle through the sacral hiatus into the epidural space at the sacral canal (Figs. 68-9 and 68-10). The patient is placed in a prone position. The legs are slightly abducted and feet turned inward to separate the gluteal fold to facilitate palpation of the sacral cornu. The sacral skin is prepped and draped in a sterile manner. AP imaging can be used to visualize the location of the

**FIGURE 68-9.** Caudal epidural injection. Needle tip in the sacral canal. Note the “smoke up the chimney” pattern of contrast in the epidural space of the sacral canal.

**FIGURE 68-10.** Caudal epidural injection. AP view demonstrating contrast in a “Christmas tree” pattern within the epidural space.

sacral hiatus. Alternatively, lateral imaging is used to view the bone defect, consistent with the opening of the sacral hiatus. The skin and the tissues overlying the sacral hiatus are anesthetized with 1% lidocaine. A 22- or 25-gauge spinal needle of appropriate length or a Tuohy epidural needle is inserted into the sacral hiatus. Loss of resistance can sometimes be felt upon needle penetration through the sacral ligament. Several milliliters of the contrast are injected in order to produce a sacral epidurogram to note the level that the contrast reaches. In the lateral view, a typical epidural contrast spread within the sacral canal resembles “smoke up a chimney” (Fig. 68-9), and in the AP view, it often looks like a “Christmas Tree” (Fig. 68-11).

**FIGURE 68-11.** Right L5 TEI. Injecting 0.5 mL of contrast outlined the right L5 spinal nerve. However, contrast also spread through the epidural space and outlined the right S1 nerve root as well.

If a vascular pattern is observed, the needle should be withdrawn and redirected. Upon proper positioning, a mixture of 10 to 20 mL of solution containing 80 to 125 mg of preservative-free methylprednisolone or other equivalent doses of corticosteroid, preservative-free normal saline, and preservative-free 1% lidocaine is slowly injected into the epidural space through the spinal or epidural needle.

## TIMING, FREQUENCY, DOSE, AND VOLUME OF EPIDURAL INJECTIONS

### Comment

Optimal timing of ESIs is unknown, although there is evidence of better benefit if ESIs are performed within 3 months of radicular pain onset (36,37). The general consensus is that most patients with radicular symptoms should undergo a few weeks of treatment including oral medications, physical therapy or manual medicine, and relative rest from activities that exacerbate their pain, before undergoing ESIs (3,23,26). If a patient does not have success with such a program, or if the therapy cannot progress because the patient’s pain is too severe, an ESI is indicated for pain control. In contrast, ESIs can be considered earlier in patients with severe radicular pain not responding to even opioid medication or with pain that is significantly interfering with a patient’s sleep and/or function (26,28). Early ESIs also carry the theoretical benefit of controlling inflammation at an early stage (5,7,38) and possibly preventing permanent neural damage such as nerve fibrosis from prolonged inflammation (8). A study demonstrated that an ESI has higher efficacy (>75% pain relief) for patients with radicular pain within 3 months duration, whereas less benefit was found in patients with sciatica longer than 7 months (39). Another study compared epidural injections with bupivacaine alone versus injections of bupivacaine with methylprednisolone in patients with lumbar radicular pain longer than 6 months in duration. At 3-month follow-up, both treatments reduced pain but there was no additional benefit with corticosteroids (40).

The time interval between epidural injections should vary depending upon the steroid preparation used. Because injected methylprednisolone is reported to remain *in situ* for about 2 weeks (41), the clinician should probably consider waiting for about 2 weeks before fully assessing a patient’s response or administering a repeat injection.

Studies have suggested that the total maximum methylprednisolone dose should be about 3 mg/kg of body weight because excessive salt and water retention can occur at doses above this due to the mineralocorticoid properties of corticosteroids. In general, it is felt that up to three to four ESIs within a year may be performed if clinically indicated (23). Some clinicians schedule and proceed with a series of three ESIs regardless of the clinical response to the first preceding injection(s). Although the efficacy of this approach is unclear, as there are no medical outcome studies to support or refute such a regimen, it may be best to reassess the response to a

given injection at the time of an intervening office visit before proceeding with another injection. Using this approach, the clinician can determine if another injection is still needed and can more readily alter their planned injection technique, rather than trying to make this assessment at the time of the scheduled injection itself.

Recommended injection volumes and the corticosteroid doses are dictated mainly by the approach used as shown in Tables 68-1 and 68-2 (23,25,26,29). The epidural steroid can be injected in a preservative-free diluent such as lidocaine (1% to 2%) or normal saline (25,28,29). In the cervical spine, it is recommended that local anesthetics and steroids be injected separately to prevent a potential embolus of poorly dissolved steroid particles within a local anesthetic diluent. A recent study demonstrated that a nonparticulate dexamethasone has similar efficacy compared with particulate triamcinolone, and carries the lowest potential risk of embolization with inadvertent intravascular injection when used in ESIs (41).

## FLUOROSCOPIC GUIDANCE AND CONTRAST

Fluoroscopic guidance and contrast enhancement are essential for accuracy when performing epidural injections (43). Published data show that even in experienced hands, epidural injections without fluoroscopic and contrast-enhanced guidance (i.e., “blind injections”) often result in inaccurate placement (Table 68-3) (43). These misplacements include the needle being inadvertently positioned into the subarachnoid, intravascular (Table 68-4), or subcutaneous regions (caudal approach) or fascial plane superficial to the ligamentum flavum for interlaminar ESI. Misplacement into the subarachnoid or intravascular regions has major potential safety implications, particularly for those injections that include local anesthetics as part of the injectate. Use of detection of flash back of blood in the needle hub to gauge the intravascular placement of needle is not a reliable substitute for looking for a vascular pattern after contrast injection (44). Although injection accuracy should also logically affect efficacy, there is very limited data on the efficacy of fluoroscopic-guided ESIs compared with blind ones. One such study demonstrated that fluoroscopic-guided transforaminal ESIs provided better pain relief than blind interlaminar ESIs (45). ESIs using fluoroscopic guidance have also been shown to reduce procedure-related complications compared to non-image-guided injections (46–48).

As a result of these factors, it is recommended that ESIs be performed under fluoroscopic guidance and with radiographic contrast, documenting appropriate needle placement in order to improve their accuracy, and by extension their safety and efficacy (49).

### Efficacy of Epidural Injections

Recent studies have demonstrated good efficacy of lumbar ESIs when proper needle placement is confirmed by using fluoroscopic guidance and radiographic contrast (50,51). A meta-analysis of 12 published randomized controlled trials concluded that ESIs are effective (52). In a systematic review of randomized trials on lumbar epidural injections, Abdi et al. concluded that there was moderate evidence that caudal and TEIs are effective in providing long-term (>6 weeks) pain relief and limited evidence for the effectiveness of lumbar interlaminar ESIs (30). Other studies have suggested that 60% to 75% of patients receive some relief after ESIs (53,54). Benefits include relief of radicular pain and low back pain (generally relieving leg pain more than back pain), improved quality of life, reduction of analgesic consumption, improved maintenance of work status, and a decreased need for hospitalization and surgery in many patients (27,50–56). One study showed no difference in analgesic use in patients with sciatica who had received three ESIs (58). Another study reported that patients were more likely to start taking opioids and more likely to receive surgery after receiving multiple (>3) injections than patients receiving fewer injections (59). However, the population of patients receiving multiple steroid injections was more likely to have had more advanced disease such as spinal stenosis.

A prospective cohort study was conducted on cervical TEIs for both neck pain and radicular pain from herniated discs or spondylosis. Twenty-one such patients awaiting surgery received cervical TESI 2 times, at 2-week interval with 12 months follow-up. All patients had reduction in neck and radicular pain, and five of these patients cancelled the surgery (59). In contrast, a prospective randomized study involving 20 patients with cervical radicular pain confirmed by selective nerve root block (SNRB) and with magnetic resonance imaging (MRI) evidence of corresponding segmental pathology demonstrated that there was no difference in radicular pain

reduction between steroid/local anesthetic and saline/local anesthetic groups at 3-week follow-up (60). A limitation of this study, however, was that it only involved small numbers of patients and that it is unknown whether saline/local anesthetic is a true control.

There are more studies in support of ESIs for low back pain (7,8,42,53–55) than there are negative studies (56). Problems with some of these supportive studies, however, include the fact that most of these studies did not use fluoroscopy and radiographic contrast to document accurate placement of the injected substance into the epidural space. Furthermore, many of these injections were not performed at the presumed level of pathology, even though this has been demonstrated to be critical to the success of ESIs (61). These methodologic problems are likely contributing factors to the mixed assessment that ESIs have received. A review of six prospective randomized clinical trials of fluoroscopic-guided transforaminal ESIs, selective nerve blocks, or periradicular nerve injections concluded that there is moderate (level III) evidence that TESI are safe and effective in reducing radicular pain. However, more prospective, randomized, placebo-controlled studies using sham procedures are needed to provide more conclusive evidence for the efficacy of TESI in treating lumbar radicular symptoms (62). A recent review article concluded that with proper patient selection, ESIs are a reasonable alternative to surgery for short-term pain relief, reduced medication use, and increased patient activities while awaiting natural recovery (63).

Aside from technical considerations, response to ESIs has been shown to be related to several other factors such as the type and quantity of steroid preparation used, volume of injectate, underlying pathophysiology, and the duration of symptoms (23,26,28). In general, radicular pain or radiculopathy induced by herniated nucleus pulposus appears to respond better to corticosteroid injection than that induced by spinal

**TABLE 68.4** Incidence of Intravascular Uptake (IVU) Associated with ESI

	Lumbar Interlaminar	Caudal	Lumbar Transforaminal	Cervical Transforaminal
IVU	1.9%	10.9%	11.2%	19.4%

Data from Carrette S, Leclaire R, Marcoux S, et al. Epidural corticosteroid injections for sciatica due to herniated nucleus pulposus. *N Engl J Med.* 1997;336:1634–1640.

stenosis. There is essentially no literature that correlates the type of disc herniation with the response of ESIs. It is the authors' collective experience and observations that patients with large lumbar disc herniations obliterating the neuroforamen or extraforaminal herniations often have less benefit from ESIs. One study demonstrated that radiculopathy induced by the combination of spinal stenosis and disc herniation has less favorable outcome with ESI. In lumbar spinal stenosis, the efficacy of ESI correlated with the degrees and the levels of stenosis categorized by MRI (64). Patients with single-level lumbar spinal stenosis generally respond better than those with multilevel lumbar spinal stenosis. ESIs provide better efficacy in reducing pain and opioid consumption for patients with mild to moderate rather than severe stenosis. But a prospective cohort study with 12-month follow-up in patients with severe degenerative lumbar spinal stenosis found that fluoroscopic-guided and contrast-enhanced caudal ESIs reduced bilateral radicular pain and improved standing and walking tolerance (65). In contrast to radiculopathy due to herniated discs and/or spinal stenosis, radiculopathy caused by epidural scar tissues or trauma such as nerve root stretch injury often responds poorly to ESI.

A recent prospective, randomized study on lumbar TESI demonstrated positive efficacy in treating radicular low back pain. The success rate for TESI is 84%, compared to 48% with trigger point injection, at 1.4 years of follow-up (66). Another prospective, randomized controlled clinical trial compared perineural (transforaminal) epidural injection with conventional posterior (interlaminar) epidural injection with steroid, and perivertebral injection with local anesthetic as a control group (27). The result demonstrated that perineural injection was the most effective approach. Both perineural and conventional epidural injection with steroid were better than that with saline alone (27).

Uncontrolled studies have generally reported favorable outcome of cervical epidural injections for cervical radiculopathy with structural abnormalities such as cervical disc herniation (66,67) and spondylosis (68). However, the prospective, randomized, blinded and controlled clinical trials on the outcome of cervical and thoracic epidural injections have not been reported yet in the peer-reviewed literature.

At the time of this writing, there have been no prospective randomized trials on thoracic ESIs that have been published in the peer-reviewed literature.

Patients should be educated that ESI alone may not be the only solution to give them long-term benefits. ESI is just one of many nonoperative treatments used to treat low back pain or radicular symptoms. Other treatments may include short-term bed rest; medications (e.g., analgesics, muscle relaxants); a properly designed program of physical therapy; and management of any psychological, financial, marital, and work-related problems. A comprehensive treatment approach is likely to produce better outcomes for patients with low back pain than any single modality used in isolation (23,26,51). Recently published research on the outcome of ESIs has supported this notion of multifaceted treatment (50,69).

## Recent Advances and Investigations on the Management of Radicular Pain

A study was performed on lumbar TEIs for radiculopathy using autologous conditioned serum (ACS) containing enriched IL-1 antagonist. The ACS group showed statistical superiority over both triamcinolone groups (5 and 10 mg) with regard to the VAS score for pain from week 12 to the final evaluation at week 22, statistical superiority at week 22 compared to the triamcinolone 5 mg group, and no significant difference compared to the 10 mg triamcinolone group. This is an exciting finding, as autologous blood is not associated with the same side effect concerns associated with corticosteroids, and theoretically can be used more frequently than corticosteroids. Additional studies are needed to confirm this finding (70).

An animal study examined the potential benefits from anti-TNF- $\alpha$  therapy in reducing neurotoxic effects induced by the nucleus pulposus on neuronal tissues (71). Two open-label human clinical trials, one using intravenous infliximab (a monoclonal antibody against TNF- $\alpha$ ) and the other using (etanercept) a soluble TNF- $\alpha$  receptor antagonist, in patients with sciatica from disc herniation demonstrated significant efficacy in pain reduction (72,73). Although these basic science and human studies initially implied potential clinical use of anti-TNF- $\alpha$  medication as a treatment for patients with radiculopathy due to disc herniation, there were disappointing long-term findings related to the evaluation of the efficacy of an anti-TNF- $\alpha$  treatment versus a placebo injection in disc herniation-induced sciatica in a randomized controlled setting. Specifically, 3-month results showed no difference in the patient-reported symptoms or in the more objective outcomes (SLR, days on sick leave, discectomies) between intravenous infliximab 5 mg/kg and placebo (74). The 1-year results also confirmed the earlier findings (75). Clearly, further studies using multiple intravenous infusion of the anti-TNF- $\alpha$  agents or epidural injection of the similar substances are necessary to clarify any efficacy of anti-TNF- $\alpha$  treatment in radicular pain.

## Safety and Complications of Epidural Injections

A retrospective cohort study reviewing the immediate complications of 2,217 patients who received selective lumbar nerve root blocks under fluoroscope, reported a 5.5% minor complication rate (76). When performed by a skilled, experienced clinician within an appropriate setting and on carefully selected patients, the chance of a significant complication from an ESI is remote (23,25,26,77–83). Like any procedure that punctures the skin, bleeding and soft tissue infection are potential but rare risks. More common risks of epidural injection are acute back pain, postural puncture headache (0.5% to 1% for lumbar interlaminar and 0.6% for caudal epidural injections), nausea, vomiting, dizziness, vasovagal reactions, and epidural hematoma (0.001%) (23,25,26,29). Nerve root injury, arachnoiditis, and meningitis also have been reported but are very rare. Lumbar transforaminal and caudal epidural injections were associated with 9.6% and 15.6% of minor complications, respectively (82,83). Anterior spinal cord syndrome has been reported after lumbar transforaminal ESIs, presumably due to

inadvertent needle contact with, or local anesthetics induced spasm of, the artery of Adamkiewicz. Although the artery of Adamkiewicz is usually located on the left side from T9 to the L3 segments, anterior cord syndrome has been reported in transforaminal ESI as low as the S1 level. Other possible mechanism of spinal cord injury related to ESIs include embolism of the injected corticosteroid particles causing spinal cord ischemia. Although rare, spinal cord injuries have been reported due to cervical and thoracic epidural injections from direct needle trauma, presumed radicular artery spasm, or steroid particle embolization (84–87). Therefore, transforaminal ESIs, especially cervical TEIs, should be performed by the most skilled and highly experienced injectionists. Real-time fluoroscopic imaging during contrast injection should be employed. Digital subtraction angiography may provide an additional safety margin for the prevention of inadvertent intra-arterial injection. Dexamethasone should be chosen as the steroid for transforaminal ESIs due to its small particle size among the various corticosteroid preparations. A recent study has demonstrated that dexamethasone and the larger particulate-sized methylprednisolone (88) have essentially the same efficacy in cervical epidural injections (89).

Corticosteroid-induced adrenal insufficiency has been reported. For example, mild hypothalamic-pituitary-adrenal (HPA) axis suppression has been reported from 1 to 3 months after receiving a total of three ESIs (once weekly) with 80 mg of triamcinolone (Aristocort) in 7 mL of 1% lidocaine (90).

## SELECTIVE NERVE ROOT BLOCK

### Diagnostic Nerve Root Block

Because of the overlap pattern of dermatomal innervation and the anatomic variants of spinal nerves, clinical history and physical examination alone are often not sufficient to accurately diagnose the segmental level of a spinal nerve lesion. In addition, current imaging studies and electrodiagnostic tests have limited sensitivity and specificity in reaching a conclusive diagnosis of radicular pain at a specific spinal level. Therefore, a diagnostic SNRB can be an important test with respect to providing a physiologic diagnosis of the level of radicular pain. By selectively depositing a limited volume of local anesthetic directly around the spinal nerve rather than in the epidural space, pain relief after the SNRB identifies the spinal nerve blocked as the involved level. A diagnostic SNRB is indicated when imaging and/or electrodiagnostic testing studies are not corroborative with the clinical findings, or these tests demonstrate multilevel pathology and the exact pain generators are unclear. Studies reveal that a diagnostic SNRB is 87% to 100% accurate when intraoperative findings are used as the gold standard (77–79). Surgery performed at the positive SNRB level had higher success rate than surgery done at a level with a negative SNRB in the lumbar spine (80). In the cervical spine, SNRB also helped guide with a high level of success the evaluation of radicular pain in the multilevel degenerative cervical spine and subsequent surgery (91).

A diagnostic SNRB is performed with the needle tip directed to the posterior lateral portion of the neuroforamen, as for a transforaminal ESI. However, for a selective spinal nerve block, the needle tip should remain outside the neuroforamen pointing at the 5 o'clock position of the pedicle above for a left-sided SNRB or at 7 o'clock for a right-sided SNRB. The needle tip should also be localized immediately lateral to the superior articular process. Special care should, therefore, be exercised not to impale or transfix the exiting spinal nerve and it is contraindicated to inject steroid or local anesthetics directly into a spinal nerve due to their neurotoxic effects. The patients should be examined before the injection to document the maneuvers and activities that produce radicular pain. The same provocative maneuvers or activities should be repeated for comparison after the diagnostic injection. Selective spinal nerve block as a diagnostic procedure is considered positive when the patient's radicular symptoms are reproduced upon gentle needle contact with the nerve sheath, followed by relief of the radicular pain after diagnostic blockade with local anesthetic.

Despite the apparent advantages of diagnostic selective spinal nerve block, the test has several limitations. Because of the overlap of the dermatomal distribution, blockade of one segment will not necessarily produce clear-cut sensory changes. Second, because the anesthetic blockade is placed at the spinal nerve, a successful block can impede pain transmission not only from the spinal nerve but also from sites distal to the spinal nerve. Furthermore, the specificity of the blockade also depends on the spread of the injectate and the exact location of the needle tip. One study demonstrated that 1 mL of injected contrast in an L4 SNRB spread onto the L5 nerve root in 46.1%, and 1 mL of injected contrast in an L5 SNRB spread onto an S1 nerve root in 57.7% of subjects (92). If the needle tip is placed too close to the neuroforamen, even 0.5 mL of injectate can spread to the adjacent nerve root level through the neuroforamen, thus compromising the specificity of the segmental test (Fig. 68-11). However, the efficacy of blockade with anesthetic less than 0.5 mL is questionable. A study that utilized multi-slice computed tomography (CT) revealed that only 0.6 mL of injectate with contrast during cervical TEIs could be accepted as being selective enough for diagnostic investigations (93). It appears that a volume somewhere between 0.5 and 1 mL of local anesthetic should be used in performing an SNRB. More randomized, controlled studies are needed to determine the optimal volume of injectate for a diagnostic selective spinal nerve block and to ascertain the true value of a diagnostic SNRB in aiding with the selection of appropriate patients for spinal decompression surgery.

## CONCLUSIONS

ESIs are effective treatment for radicular pain, at least in the short-term period, and particularly in the lumbosacral region. The use of fluoroscopic guidance and contrast enhancement can improve injection accuracy and thus presumably improve

safety and effectiveness. While ESIs are often reserved for patients who have failed to improve with other nonsurgical treatments, performing them earlier may further enhance their effectiveness. Further research is needed regarding the frequency of repeat injections.

## ZYGAPOPHYSEAL JOINT INJECTION AND RADIOFREQUENCY MEDIAL BRANCH NEUROTOMY

### Introduction

The prevalence of lumbar zygapophyseal joint (Z-joint) pain has been reported to be approximately 6% in a primary care setting (94). However, in a tertiary spine center, lumbar Z-joint pain has been reported to range from 15% in younger individuals (96) to 40% in older populations (98) with chronic low back pain. In individuals with chronic neck pain after a whiplash injury, Z-joint pain occurred in approximately 50% of patients (99,100). More recent literature examining 500 patients has reported a prevalence of 55% cervical facet joint pain, 42% thoracic facet joint pain, and 31% lumbar Z-joint pain in patients with *chronic* spine pain identified with a double block model as described later (95). Lumbar facet joint pain has been reported in 16% of patients with *chronic postsurgical* lumbar spine pain (97). Studies of a larger population using a dual anesthetic block paradigm may be helpful in further identifying the prevalence in the general population for both acute and chronic low back pain.

### Anatomy

Z-joints are pairs of small synovial joints in the posterior aspect of the spine, formed when the inferior articular process of one vertebra articulates with the superior articular process of the subjacent vertebra. Each lumbar Z-joint has a 1 to 2 mL capacity (101). Cervical and thoracic Z-joints can hold volumes of less than 1 mL (103) and 0.5 to 0.6 mL (104,105), respectively.

The Z-joint at C2-3 is innervated by the third occipital nerve from the superficial medial branch of the C3 dorsal ramus. Below the C2-3 Z-joint, each cervical Z-joint is innervated by the medial branches from the level above and below. The medial branches wrap around the articular pillar transverse processes. The C7 medial branch is located higher, as it is pushed up by the base of the transverse process. The joints between C0-1 (atlanto-occipital) and C1-2 (atlantoaxial) joints are technically not Z-joints, due to their anterior location. They are innervated by the anterior rami of C1 and C2, respectively. Significant variability in the location of the medial branches has been reported, particularly with regard to the anatomy in the cervical spine (102).

The medial branches innervating the thoracic Z-joints have a different course in relation to the transverse processes (105). The thoracic medial branches instead wrap around the junction between the transverse process and the superior articular process. As in the lumbar spine, they often exit in the

middle portion of the intertransverse space, and they typically cross the superolateral corners of the transverse processes and then pass medially and inferiorly across the posterior surfaces of the transverse processes. Furthermore, at mid-thoracic levels (T5-8), the inflection occurs at a point superior to the superolateral corner of the transverse process. Therefore, the superolateral corners of the transverse processes are generally the more accurate target points for diagnostic blockade or radiofrequency denervation of the thoracic medial branches.

In the lumbar spine, each Z-joint is innervated by two medial branches of dorsal rami; one from the same level and the other from the level above (106). For example, the Z-joint at L4-5 is innervated by the medial branches of the L4 and L3 dorsal rami. The medial branches travel along the junction of transverse process and superior articular process. After exiting the mamilloaccessory notch covered by the mamilloaccessory ligament, the medial branches send branches to innervate the same level of the Z-joint and the Z-joint below. However, the L5 dorsal ramus crosses the groove between the sacral ala and the superior articular process of the sacrum. The L5 medial branch to the L5-S1 Z-joint is very short because it does not branch out until it comes just under the L5-S1 Z-joint.

It is important to remember that the lumbar medial branch rests on the subjacent level rather than the same level of the transverse process. For example, the L3 medial branch rests on the L4 transverse process rather than on the L3 transverse process (Figs. 68-12 and 68-13). Therefore, to denervate the L4-5 Z-joint, it is necessary to target the L3 and L4 medial branches, which rest on the junction of L4 and L5 transverse processes and superior articular processes, respectively. One exception is the blockade or denervation of the L5 medial branch. Due to the short branch below the Z-joint, denervation of the L5 medial branch can only be performed by destruction of the L5 dorsal ramus proper at the groove between the sacral ala and the superior articular process.

### Pathophysiology of Z-joint Pain

The Z-joint is a well-innervated structure. The Z-joint capsule contains both nociceptive and mechanosensitive receptors (101,106–108). Immunocytochemical studies have demonstrated that the Z-joint capsule or synovial folds contain substance P, calcitonin gene-related product, vasoactive intestinal polypeptide (VIP) and neuropeptide, and tyrosine hydroxylase (101,107,108). Ostensibly, the Z-joint capsule is a potential pain generator if it is injured. In addition, like any synovial joints, Z-joints can develop synovitis under certain circumstances.

Typical Z-joint pathology often derives from pathologic mechanical stress or inflammation. In the lumbar spine, the sagittal orientation of upper lumbar Z-joints and the relative lateral oblique orientation of lower lumbar Z-joints make them vulnerable to injury from extension and torsion forces.

In the cervical spine, both human and animal studies of whiplash injuries have demonstrated evidence of multiple pathologic findings, including Z-joint capsule tearing, intra-articular hemorrhage, articular cartilage, muscle injury, and

**FIGURE 68-12.** AP view of left L5-S1 Z-joint (facet) arthrogram. Notice the contrast pooling in the superior and inferior articular recesses. This 33-year-old man injured his low back lifting a 70-lb piece of metal overhead. Unable to sustain the weight, he extended his low back obliquely to the right side to drop the metal. He felt a “pop” in his left low back and sustained persistent significant left low back pain. Several minutes after this left L5-S1 intra-articular Z-joint injection with 0.5mL of 1% lidocaine, his low back pain was completely abolished.

subchondral bone fracture (110). These pathologic changes can serve as a basis of pathologic nociception and neck pain. However, none of these pathologies can be detected with conventional imaging studies (110).

Patients with lumbar Z-joint pain often have more pain in the lateral aspect of the low back unilaterally or bilaterally but not centrally (111). Pain can often be made worse with oblique extension of the lumbar spine (111,112). Pain is often worse after overnight rest or inactivity. Local tenderness and “muscle spasm” over the involved Z-joint are frequently noted. Although Z-joint pain can present with referred pain, groin pain or thigh pain, neural tension signs are negative and there are generally no neurological deficits, though recently a study where a rat model was used to induce Z-joint inflammation has documented associated radiculopathy as a possible sequela (109). Patients with cervical Z-joint pain experience pain located in the axial cervical areas. However, several studies have failed to demonstrate any pathognomonic physical exam findings of Z-joint pain (111,112). Imaging studies are also unable to confirm or refute the diagnosis of Z-joint pain (110,113,114).

### Indications

Given the lack of a clinical diagnostic gold standard, clinicians have used regional anesthesia to identify Z-joint pain. Abolishment of low back pain after anesthetic Z-joint injection

**FIGURE 68-13.** AP lumbar MBB at the right L2, L3 and L4 vertebral levels, demonstrating needle tips and contrast injected at the base of SAPs and the transverse processes.

or medial branch block confirms the Z-joint as the pain generator (Figs. 68-14 and 68-15). Z-joint injection is indicated in patients with acute back and neck pain of suspected Z-joint origin, with no evidence of neurologic deficits, and whose pain pattern resembles that evoked in normal volunteers upon stimulation of their Z-joints. However, since the majority of acute back and neck pain, including Z-joint pain, will resolve in several weeks, the injection is often reserved for individuals

**FIGURE 68-14.** Oblique view of left L4-5 Z-joint injection showing the needle tip inside the Z-joint space.

**FIGURE 68-15.** Oblique view demonstrating blocks of right L1, L2 and L3 medial branches at the right L2, L3 and L4 pedicles, viewed as the “eyes of the Scottie dogs”, at the base of the SAPs and transverse process where the medial branches are located.

with severe pain that has failed to respond to 4 to 6 weeks of conservative therapy including oral analgesics, directed physical therapy, and relative rest. Fortunately, injection can be performed earlier if pain is inhibiting therapy progress.

### Contraindications

As is true of all spinal injection procedures, Z-joint injections are contraindicated in individuals with the following conditions: infection, bleeding diathesis, pregnancy (for use of fluoroscopy), allergy to the medications to be injected (contrast medium, local anesthetics, corticosteroid), and unstable medical conditions such as unstable angina or poorly controlled hypertension or diabetes mellitus. Injections are elective procedures, so an effort should be made to properly select patients so as to ensure safety and optimize outcome.

### Techniques

For lumbar Z-joint injection, the patient is placed in a prone position with a pillow under the abdomen to distract the Z-joint. After sterile preparation and skin draping, intermittent fluoroscopic views are used to identify the level of the Z-joint. For the L5-S1 level, the fluoroscope is tilted in a caudad direction to accommodate the lumbar lordosis, and rotated ipsilaterally until the joint space first comes into view, which is the posterior opening of the Z-joint, that is, the needle entry point. Although further rotating the image intensifier will more clearly visualize the Z-joint space, the visualized joint space at this angle is actually the middle or anterior Z-joint opening, not the posterior opening which is the injectionist's target. For upper lumbar Z-joint injections, it may require less oblique

rotation to better visualize the Z-joint space. The needle entry site is marked with a metal instrument. The skin and the underlying tissues are infiltrated with 1% lidocaine. For diagnostic Z-joint injections, the underlying tissues should not be infiltrated with anesthetic in order to maximize injection specificity. A 22- or 25-gauge 3.5 in. spinal needle is then inserted at the anesthetized site and directed toward either the superior or inferior articular processes of the targeted facet joint using a “tunnel view” technique by which the entire needle shaft is paralleled to the fluoroscopy beam in such a way that the needle hub appears as a dot. Once the needle contacts the bone, the tip of the needle is then “walked” off into the Z-joint space. Occasionally, due to the osteoarthritic changes, the needle cannot gain entry. The needle can then be directed into the inferior articular recess just off the lower margin of the articular processes. Once the needle is felt to be in the articular space or to have penetrated the Z-joint capsule, 0.2 to 0.3 mL of the water soluble and nonionic contrast is injected to outline the Z-joint and to confirm that the needle tip is not located inside the vascular or epidural space. For therapeutic benefit, 1.0 mL of a mixed solution containing 20 mg of methylprednisolone acetate and 1% lidocaine is slowly injected into the Z-joint.

### Medial Branch Block

For lumbar medial branch blocks, skin preparation and C-arm fluoroscope positioning are essentially the same as for Z-joint injections. The difference is the target, which is the “Scottie dog’s eye” rather than “ear,” because the former represents the anatomical site where the medial branch is situated whereas the latter represents the articular processes forming the Z-joint. After local skin is infiltrated with 1% lidocaine, a 22- or 25-gauge 3.5 in. needle is inserted and directed until the needle touches the middle portion of the “Scottie dog’s eye.” The fluoroscope is then turned to the cross table or lateral view; the needle should be located at the site posterior to the spinal lamina. At the anteroposterior (AP) view, the needle tip should be at or slightly medial to the lateral margin of the superior articular process. At this point, the needle bevel should be turned to face medially, and 0.2 to 0.3 mL of the contrast is injected under real-time fluoroscopy to ensure that a vascular pattern or neuroforamial spread upon the dye injection has occurred. To ensure block specificity, less than 0.5 mL of either 2% lidocaine or 0.5% bupivacaine is used to block each medial branch.

For block of the L5 dorsal ramus, the fluoroscope should be rotated ipsilaterally oblique about 10 to 15 degrees. The needle is then directed in “tunnel view” down to the junction at the superior articular process of the S1 vertebra and the ala of the sacrum. In the AP view, the needle tip should be at the lateral margin of the S1 superior articular process.

### Efficacy

#### Diagnostic Z-Joint Injection or Medial Branch Block

The literature has demonstrated that Z-joint injections and medial branch blocks can be used for the diagnosis of Z-joint pain with comparable sensitivity and specificity (Fig. 68-16)

**FIGURE 68-16.** Lateral view of cervical Z-joint injection, with the arthrogram demonstrating the typical dumbbell shape.

(115–118). A medial branch block may be relatively easier to perform with less trauma to the Z-joint. In the cervical spine, medial branch blockade has been shown to be a valid technique for the diagnosis of Z-joint mediated pain (119). Overall, medial branch blockade has a reported 89% specificity and 11% false-negative rate (118).

Since the degree of pain relief is a patient's subjective response, Z-joint injection or medial branch blockade is susceptible to a placebo effect. Other possible causes of false-positive studies include inadvertent anesthetic spread to pain generators outside of the Z-joint. Research has shown false-positive rates of 27% to 38% for lumbar blocks, 27% to 63% for cervical blocks, 55% for thoracic blocks, and a 32% placebo effect (95,112,120,121). To minimize false-positive rates, various clinicians have advocated evaluating the response to injecting anesthetics of varying anesthetic durations as well as possibly performing a control injection with saline placebo. A true-positive response is considered to be pain relief lasting for 1 to 2 hours with 2% lidocaine, and 3 to 4 hours with 0.5% bupivacaine, but no effect with saline. However, such a triple block scheme requires three separate procedures and is thus time consuming and costly. Ethical issues arise if a patient accepts the procedural risks and financial costs expecting a therapeutic injection, only to receive a placebo injection. A compromise is to perform a "double block paradigm" using two local anesthetics with different durations of action, one on each of two separate occasions. If each of the two injections relieves pain for the duration expected for the anesthetic used, Z-joint pain can be reliably diagnosed. Published studies have validated this dual blockade paradigm, using comparative local anesthetics for medial branch blocks to anesthetize Z-joints, which constitutes a viable alternative to normal saline controls (100,122).

Potential causes of false-negative responses include venous uptake of the injected anesthetic, aberrant innervation of the target Z-joint, and other technical issues. Since both intravascular injection and epidural spread of injectate can reduce the injection specificity, fluoroscopy plays an important role in maximizing outcomes.

If injection is being performed solely for diagnostic, not therapeutic, purposes, then only local anesthetic should be injected, without corticosteroid. Regarding the placebo-controlled blocks, a positive diagnosis was recorded only if the patient's pain was completely and reproducibly relieved by each of the local anesthetic but not via the normal saline.

As stated above, double block with local anesthetics of different durations on two separate occasions can reduce (although not eliminate) the false-positive response and placebo effect (122). What constitutes a positive diagnostic response remains the physician's subjective judgment. For a true concordant response with comparative blocks (100), the patient should obtain complete pain relief with a duration that is consistent with each particular anesthetic solution, though recent published placebo-controlled studies have used a criterion of at least 80% pain relief. This concordant response criterion for identifying Z-joint pain yields a good specificity of 88%, but only marginal sensitivity of 54%, thus suggesting significant false-negatives (100). Expanding the comparative blocks diagnostic criteria to include all patients with reproducible relief, irrespective of duration, increases sensitivity to 100% but lowers specificity to 65% (100). Whether the criterion should be structured to more aggressively prevent false-positive responses versus to prevent false-negative responses may depend on what subsequent treatment will be based on the determination. For additional treatments that can irreversibly alter the patient's anatomy (e.g., via surgery or radiofrequency ablation [RFA]), preventing false-positive responses becomes increasingly important (100).

Using the dual block technique in patients with chronic low back pain, lumbar Z-joint pain was demonstrated in 15% of younger patients and 40% of older patients (96,98). In chronic neck pain after whiplash injury from motor vehicle injury, Z-joint pain occurred in 54% of patients (99). Another study of patients with chronic neck pain for more than 6 months demonstrated that the prevalence of Z-joint pain was 36% (123). The C2-3 and C5-6 Z-joints were found to be the most common symptomatic joints (99,123). The C2-3 joint was found to be a pain generator in 50% of patients with chronic cervicogenic headache after a whiplash injury (99). It is interesting that using the intra-articular and/or medial branch block, studies have demonstrated that the coexistence of Z-joint pain and discogenic pain in lumbar region is only 4%, while in the cervical spine it is 40% (124,125).

Caution should be exercised using provocation of pain as a sole diagnostic criterion for patient undergoing a diagnostic lumbar Z-joint injection. One study has demonstrated

no significant correlation between pain provocation during Z-joint injection and the analgesic response (126).

### Therapeutic Effect

The therapeutic benefit of Z-joint injection with corticosteroids remains controversial (127). A past study has suggested positive efficacy of C2-3 Z-joint corticosteroid injections for cervicogenic headache after a whiplash injury (128). Controlled studies have failed to demonstrate such efficacy although the studies had various design flaws (Table 68-5), including the use of saline as a placebo, patient selection bias without using a double block technique, and injection in isolation of other treatments. Selection of patients without using the double block paradigm may potentially include those patients with false-positive results. Finally, injection is not recommended to be used in isolation of other treatments. Rather, when tolerable, patients should be involved in a directed therapy program if they experience significant pain reduction (therapeutic window) after the injection.

A recently published systematic review of the literature from 2004 to 2006 has demonstrated strong evidence for diagnostic injections in the cervical and lumbar spine and moderate evidence for diagnostic injections in the thoracic spine (115). Another published review from 2007 has noted “limited” evidence for intra-articular cervical facet joint injections and “moderate” evidence for intra-articular lumbar Z-joint injections for pain relief (129). It is interesting to note, however, that this study did conclude that there actually was moderate evidence for short- and long-term pain relief from medial branch blocks.

### Radiofrequency Neurotomy

Radiofrequency neurotomy interrupts the nociceptive afferent from the Z-joint by thermally coagulating the two medial

branches that innervate a given Z-joint. The exposed terminal portion of radiofrequency probe delivers heat at 80°C. For each Z-joint (except the C2-3 joint, which is innervated by the third occipital nerve), two medial branches need to be ablated.

### Indications

Radiofrequency neurotomy can provide relative long-term benefit symptoms from persistent or recurrent Z-joint pain despite conservative care (that have had transient benefit from Z-joint injections), and for patients with substantial (e.g., at least 80%) pain relief after dual blocks of the medial branch with two local anesthetics of different duration on two occasions.

### Technique

#### Lumbar Medial Branch Neurotomy

Since the “groove” at the junction of the superior articular process and the transverse process can be clearly viewed in a certain fluoroscopic position, this “groove view” has been proposed for the starting position of a lumbar medial branch neurotomy. Specifically, the C-arm intensifier is obliqued ipsilaterally approximately 10 to 15 degrees and tilted cephalad 20 degrees. A 22-gauge 100 mm radiofrequency probe with a 5-mm active tip is then introduced using the “tunnel view” until it contacts the bone and advanced along the “groove” where the medial branch resides. The radiofrequency probe creates an effective circumferential lesion around the probe but does so poorly distal to the tip. To avoid incomplete heating, the radiofrequency probe needs to be placed on and parallel to the path of the medial branches crossing the transverse processes. In AP imaging, the needle should be medial to the lateral silhouette of the superior articular process. A lateral view should be obtained to ensure that the

Data from Stalcup ST, Crall TS, Gilula L, et al. Influence of needle-tip position on the incidence of immediate complications in 2,217 selective lumbar nerve root blocks. *Spine J.* 2006;6(2):170–176; Manchikanti L. Cervical epidural steroid injection with intrinsic spinal cord damage. *Spine.* 1999;24(11):1170–1172.

needle is not positioned anterior to the posterior aspect of the neuroforamen. Motor stimulation using 2.0 Hz and less than 2.0 V should not induce any muscle twitching or movement in the lower extremity. A single lesion at 80 degrees celsius for 60 seconds is performed. A second and third lesion is performed after repositioning the needle 1.0 mL cephalad and caudad to ensure proper coagulation of the length of the medial branch.

### Cervical Medial Branch Neurotomy

For cervical medial branch ablation, the patient is placed in a prone position and the C-arm is tilted in a cephalad direction to obtain a pillar view. The first radiofrequency lesioning probe is inserted parallel to the articular pillar, directed down the fluoroscopic beam and slightly medial until it touches the dorsal aspect of the pillar. The needle is then walked lateral until it slips off the bone. A second radiofrequency probe is inserted with approximately 30 degrees of ipsilateral obliquity and slightly caudad so that this needle can be positioned more anteriorly. The rest of the needle advancement is the same as for the first needle. This dual needle placement positions the two probes to allow subsequent adequate denervation along the entire length of the medial branch. Prior to lesioning, a lateral view is taken to ensure that the tips of the radiofrequency probes are not anterior to the anterior margin of the articular pillars. Motor stimulation is conducted at a frequency of 2.0 Hz and at less than 2.0 V intensity. If muscle twitching or upper extremity movement occurs, this indicates that the radiofrequency probe is too close to the anterior rami and needs to be repositioned. Next, 0.5 mL of 1% lidocaine is injected through the radiofrequency cannula. A lesion is then performed at this position at 80°C for 60 seconds. The probe is then repositioned 1 mm caudad and cephalad, respectively, and two additional lesions are made for a total of six lesions using the two radiofrequency probes. A similar technique is employed for the third occipital nerve.

### Efficacy

Proper patient selection is the key for optimal outcome from radiofrequency neurotomy. One recent prospective study has demonstrated good efficacy from the procedures when patients with presumed Z-joint pain are selected using the double block paradigm with comparative local anesthetic (130). The patients were diagnosed with a lumbar Z-joint pain if they obtained at least 80% pain reduction after medial branch blocks with 0.5 mL of 2% lidocaine on one occasion and 0.5% bupivacaine on another. At 12 months following the radiofrequency medial branch neurotomy, 60% of patients achieved at least 90% pain reduction and 87% of patients had 60% pain relief. The success of denervation was seen in virtually all patients as demonstrated by post-radiofrequency needle EMG of the corresponding segmental multifidi (130). The initial population of 41 patients accepted into the study and clinically felt to have facet-mediated pain was reduced to only 15 candidates for actual RFA, which

further emphasizes the importance of double-block screening for Z-joint pain diagnosis. A recent randomized study using single Z-joint blocks for selecting patients with subsequent radiofrequency neurotomy demonstrated modest success with an average VAS pain reduction of 2.0 points in 66.7% of the lesion group versus 35.7% of sham group patients at 8 weeks to 12 months follow-up (131). An obvious concern with this study is that the criteria for a positive block mandated a relatively low threshold of only 50% pain relief, and 40 of 92 patients subjected to the diagnostic block had a positive response in this regard. This would imply a prevalence of facet joint pain higher than what has been reported in most populations. Another study showed no treatment effect at 12 weeks, as assessed by the Roland-Morris scale (2.6% change) and Oswestry scale (1.9% change) and VAS (−7.6% change) (132). Again, the known 38% false-positive rate for a single-block makes the study results and conclusions less convincing (126,133).

Efficacy of radiofrequency neurotomy for cervical Z-joint pain (other than from the C2-3 joint that was excluded from this study), has also been demonstrated in a randomized, double-blinded, and placebo-controlled trial (134,135). The patients were selected by placebo-controlled medial branch blocks. The total duration of pain relief was defined as the period until the patient judged that pain had returned to 50% of the pre-procedural level. Twenty-four patients were randomized into radiofrequency neurotomy and sham radiofrequency neurotomy (radiofrequency probes placed but radiofrequency was not turned on) groups. Fifty percent pain relief lasted 263 days in the radiofrequency group and 8 days in a controlled group. A second study of 28 patients with long-term follow-up and repeat radiofrequency neurotomy demonstrated a median duration of pain relief of 422 days. In the 11 patients who underwent repeat radiofrequency neurotomy, the median duration of pain relief was 219 days. The authors concluded that radiofrequency neurotomy provides clinically significant pain relief, and can be repeated if pain recurs (136).

Recent review articles on randomized controlled trials of radiofrequency neurotomy for spinal pain concluded that RF neurotomy was efficacious for both chronic low back pain and neck pain after flexion-extension injuries (124), and that there is evidence of moderate strength for use of RFA in the cervical and lumbar spine (129).

### Complications of Z-Joint Procedures

Potential complications of fluoroscopic-guided, contrast-enhanced lumbar Z-joint injections or medial branch blocks are rare. The most common post-procedural problem is transient pain at the injection site. However, there have been rare case reports of meningitis, inadvertent spinal anesthesia, and infection after Z-joint injections (137,138).

Recurrent back and neck pain after radiofrequency neurotomy may be due to incomplete ablation or medial branch regeneration (139). Since the dorsal root ganglia are left intact, the ablated medial branches may regenerate. Because

radiofrequency neurotomy does not permanently denervate the Z-joints or cause inherent instability in the spine, the concern of Charcot facet joint development has little ground and no such cases have been published (140). Also, because the DRG remains intact, deafferentation pain should not occur. Side effects from radiofrequency neurotomy are rare when the procedure is performed correctly but include local pain and infection.

## CONCLUSIONS

The Z-joints of the spine can be a significant source of pain. Diagnostic medial branch blockade is a valid technique for confirming the Z-joint as a pain generator. Proper selection of patients with the dual block paradigm may minimize false-positive responses and increase therapeutic efficacy for intra-articular injections. In carefully selected patients with recalcitrant symptoms, radiofrequency neurotomy of medial branches may offer long-term benefit.

## SACROILIAC JOINT INJECTION

The sacroiliac (SI) joint can be a significant source of low back pain (141–143). Etiologies of SI pain include spondyloarthropathy, crystal arthropathy, septic arthritis, trauma, and pregnancy diasthesis (144). In addition, SI joint dysfunction (pain from a biomechanical disorder without a demonstrable lesion) has been proposed as a possible etiology of SI pain (145). Among patients with chronic low back pain, a study using a single block technique of the SI joint with a local anesthetic, estimated the prevalence of SI joint pain as between 13% and 30% (141). A study on 54 patients with unilateral low back pain suspected from the SI joint, using a dual local anesthetic block technique, demonstrated an 18.5% prevalence of SI joint-based pain (142).

### Anatomy and Pathophysiology

The SI joint is a true diarthrodial joint and is innervated by nerves from the L4 through S2 levels (146). Studies on human and animal SI joint capsules demonstrated the presence of mechanoreceptors and nociceptors (147,148). The SI joint has a close anatomic relationship to the lumbosacral plexus and the L5 and S2 nerve roots. Therefore, SI joint pathology such as inflammation or chronic synovial irritation from joint dysfunction can not only serve as a pain generator, but also can potentially involve the nearby neural tissues and induce pain. Injection of the joint with contrast material in healthy volunteers produced pain that extended approximately 10 cm caudally and 3 cm laterally from the posterior superior iliac spine in a linear strip (146). Patients with pain diagrams similar to the SI joint pain mapping were confirmed as having SI pain with SI joint provocation injection (149).

**FIGURE 68-17.** AP view of right SI joint arthrogram demonstrating contrast in the posterior (medial) and anterior (lateral) joint space. This 23-year-old man complained of persistent right-sided low back pain after a front-impact motor vehicle collision. He was forcefully pressing his right foot on the brake during the collision, with resultant right SI pain. Injecting the right SI joint with 1 mL of 2% lidocaine relieved 90% of his low back pain, lasting several hours. SI joint injections can have both diagnostic and therapeutic benefits.

### Diagnosis of the SI Joint Pain

The value of clinical data from history and physical examination in the diagnosis of SI joint pain remains controversial (141–143,150,151). Although SI joint pain frequently manifests as pain in the sacral sulcus areas, SI joint pain can refer to the buttock, lower lumbar region, groin, and lower limb (152). However, none of these symptoms, signs or various provocative tests are pathognomonic for SI joint pain. Other sources of low back pain, such as lower lumbar Z-joint arthropathy or degenerative disc disease, can present similarly. By using fluoroscopically guided SI joint blocks to confirm cases of SI joint pain (Fig. 68-17), several authors have shown that clinical medical history and pain provocation tests are not reliable in the diagnosis of SI joint pain (141–143,150,151).

In a clinical trial involving 84 patients with possible low back pain from the SI joint, Dreyfuss et al. studied clinical history and the 12 physical examination tests deemed most reliable by a panel of experts for isolating SI joint pain (143). Fluoroscopically guided intra-articular SI joint injections of local anesthetic and corticosteroid were performed to confirm the diagnosis. The criterion for a positive result was the achievement of at least 90% pain relief postinjection. The study demonstrated that neither the history nor the physical examination data was of significant value in diagnosing SI joint pain (141). Maigne et al. investigated 54 patients with clinical features of chronic low back pain compatible with the origin in the SI joint with the following features: unilateral buttock pain,

tenderness over the SI joint, normal lumbar CT scan, failure of previous epidural, or facet injections (142). They applied seven “SI pain provocation tests” before and after the dual block of SI joint. To be considered diagnostic, patients had to report 100% pain relief after block with 1% lidocaine and at least 75% pain relief after block with 0.25% marcaine. There was an 18.5% rate of positive responders to this dual block. The result demonstrated that none of the SI joint pain provocation tests were able to isolate SI joint pain (142). Slipman et al. performed a diagnostic fluoroscopically guided SI joint injection in 50 consecutive patients with low back pain presumed to be from SI joint (162). A reduction of the VAS rating by at least 80% was considered a positive response to SI joint block. The authors concluded that the various SI joint provocative maneuvers were not useful in diagnosing SI joint pain (162).

A diagnostic imaging study done with bone scan was found to have low sensitivity and high specificity for diagnosing the SI joint syndrome (149). This study excluded patients with SI joint pain from inflammation, such as in a seronegative spondyloarthropathy. However, another study using single photon emission CT (SPECT) was performed in 54 patients with symptoms of low back pain of at least 3 months duration, the presence of higher erythrocyte sedimentation rate, and higher C-reactive protein levels who had not received anti-inflammatory drugs. The results demonstrated high sensitivity (97%) and specificity (90%) in diagnosing inflammatory disease within SI joints (153).

## Indications

Although exact guidelines for administering an SI joint injection are unclear, one set of guidelines is as follows: a diagnostic SI joint injection is indicated in patients with pain over the sacral sulcus who have failed to respond to 4 to 6 weeks of directed physical therapy and oral nonsteroidal anti-inflammatory agents (154,155).

## Technique

The patient is placed in a prone position. The skin over the sacral area is prepped and draped in a sterile manner. By rotating the C-arm fluoroscope slightly contralaterally, but occasionally ipsilaterally, intermittent fluoroscopy is used to identify the medial joint line when it just separates from the lateral joint line of the SI joint. Some adjustment of the C-arm in the caudal or cephalad plane may then be used to best isolate and visualize the lower portion of the SI joint. The targeted area is the small lucent area just below the joint line. The skin entry site is selected slightly lower than the targeted area, and is infiltrated with a small amount of 1% lidocaine. A 22- or 25-gauge 2.5 to 3.5-in. spinal needle is inserted and directed down to contact the ilium. The needle is then withdrawn 2 to 3 mL and redirected toward the inferior-medial aspect of the joint into the lucent area (156). Typically, the needle tip will bend if it enters the SI joint, and a tactile sense of a sliding into the joint will be appreciated (157). Applying a slight curve at the tip of the needle prior to use may help assist this process (156). A small amount of contrast is then injected to outline the SI joint. If the needle fails to plunge and no contrast flow is seen on fluoroscopy, one technique advocates

that the needle be slowly extracted a millimeter at a time, while continuing to maintain pressure on the plunger until there is a loss of resistance (157). Once an SI joint arthrogram without a vascular uptake pattern is demonstrated, anesthetic with or without steroid is injected (depending upon if the injection intent is for therapeutic or diagnostic use, respectively). One milliliter of 2% lidocaine or 0.5% bupivacaine mixed with 40 mg/mL of triamcinolone acetonide, or other equivalent corticosteroid, is injected into the SI joint (158–161). A total of no more than 2.0 mL of volume is generally injected due to the limited volume of the SI joint (160).

## Efficacy

### Diagnostic Injection of SI Joints

Because the gold standard for proof of SI joint pain is unclear, the sensitivity and specificity of diagnostic SI joint injections has not been clearly established.

Maigne et al. (142) have suggested that the SI joint block has diagnostic value only for pain from intra-articular sources, not for SI joint pain from extra-articular sources such as the periosteum, interosseous ligaments, erector spinae muscles, or fascial elements, all of which contain nociceptors and hence are possible pain generators (147,148). Therefore, an SI joint block procedure that involves injection of an agent into the extra-articular components rather than the joint cavity may show better correspondence to the clinical features. Future studies should address whether the combination of pericapsular and intra-articular SI joint injection with corticosteroid can improve outcomes.

### Therapeutic Injection of the SI Joint

The efficacy of SI joint corticosteroid injections has been reported in prospective and retrospective studies of patients with spondyloarthropathy (163,164). In a retrospective study, Slipman et al. reported a significant benefit from SI joint steroid injection in patients with SI joint syndrome (165). Thirty-one patients with chronic SI joint syndrome received an average of 2.1 fluoroscopic-guided SI joint corticosteroid injections. The average follow-up was 94.4 weeks. Of the 29 patients who completed the study, there was a significant improvement in the Oswestry disability score, VAS, and work status (165). Although these retrospective results are encouraging, there are currently no prospective studies on the efficacy of fluoroscopically guided therapeutic SI joint corticosteroid injections.

## Radiofrequency Ablation of the SI Joint

Radiofrequency ablation (RF-A) has recently been proposed as a potential long lasting treatment for SI joint pain, and has been gaining more popularity along with other nonsurgical spinal procedures. RF-A involves de-innervation of the SI joint nerves believed to be responsible for generating pain (166,167). It is indicated as a treatment for those patients who have failed more conservative measures, yet only received transient benefit from diagnostic and/or therapeutic injections of the SI joint (168). The true effectiveness of RF-A of the SI joint is unclear, as of yet (169). In contrast to RF-A in

**TABLE 68.6 Summary of RF-A of the SI Joint Studies**

Author(s)	# of Patients	RF-A Technique(s)	Outcome
Buijs et al. (174)	43	"3 puncture" technique directed at the lateral upper quadrant of S1-3 dorsal foramen, targeted to dorsal rami of L4-5 and S1-3 spinal nerves	63.2% of the patients had >50% reduction in their pain at 12 wk post RF-A
Burnham and Yasui (171)	9	"Leap Frogging" and "Strip Lesion" technique done to the L5 posterior ramus and dorsal lateral foraminal aperture of S1-3	67% of patients indicated a "very satisfied" response postprocedure at 12 wk post RF-A
Cohen and Abdi (168)	9	RF-A to L4-5 dorsal rami, and S1-3 lateral branches	100% of patients had >40% improvement in pain at 9 mo post RF-A
Ferrante et al. (166)	33	"Leapfrog" technique as high in the joint with multiple lesions around the joint	34.6% of patients had a 50% decrease of pain at 6 mo post-RF-A
Gevargez et al. (173)	38	Regional RF-A to the posterior interosseous SI ligaments and dorsal branches of L5 spinal nerves	65.8% of patients had "a substantial relief" in pain at 3 mo post RF-A
Vallejo et al. (172)	22	RF-A directed at medial branches of L4, posterior rami of L5, and lateral branches of the S1-2	72.7% of patients had a pain reduction of 50% at 3 mo post RF-A
Yin et al. (159)	14	RF-A directed at the lateral branches of the S1-3 spinal nerves	64% of patients had a reduction in pain of 50% at 6 mo post RF-A

treating lumbar spine facet-mediated pain, which directly targets the medial branches of the dorsal rami, which innervate the facet joints (170), the SI joint has complex innervations (171). Therefore, no consistent procedural technique has been described in the literature. Multiple studies have, in fact, been done using various techniques for RF-A of the SI joint, which are summarized in Table 68-6. The table shows that there are variations among the techniques used in regard to structures, nerves, and patterns of ablation to the SI joint.

The table underscores the fact that there is no standard pattern of ablation and not enough available prospective data to determine which rami or branches should be ablated, or if a pattern technique (i.e., "leap frog" vs. "strip lesion") is more efficacious. The studies do not show uniformity and additional studies to determine if RF-A is useful for treating chronic SI joint pain are warranted.

## CONCLUSIONS

The SI joint can be a common source of low back pain. Diagnostic SI injections may be more reliable than physical exam maneuvers in confirming SI pain. SI joint corticosteroid

injections may improve both pain and function. SI joint RF-A is being investigated as a potential tool for achieving lasting relief of SI joint pain.

## DISCOGRAPHY (DIAGNOSTIC DISC INJECTION)

Although still controversial, discography (diagnostic intervertebral disc injection) is both an imaging study and a provocative physiologic study for determining whether an intervertebral disc is in fact a pain generator in a given patient (Table 68-7). Inserting a spinal needle into the center of the intervertebral disc and injecting contrast dye provides both physiologic information on whether a degenerative disc is painful and on anatomic features of the intervertebral disc. There is currently no other method to establish reliably whether a disc is a patient's pain generator.

### Clinical Presentation of Discogenic Pain

Patients with lumbar discogenic pain typically have low back pain but can also have pain referred to the buttock, hip, groin, thigh, or distal lower limb. (175). Discogenic pain is typically

**TABLE 68.7 Review of Normal and Abnormal Discography Findings**

	Pain	Volume Accepted	End Point During Injection	Disc Morphology	Pain Relief After Injection of Lidocaine
Normal	No pain	1.5–2 mL	Firm	Cotton ball or bicleft	N/A
Abnormal	Concordant	Less or much more	Soft or indefinite	Radial fissure or annular rupture	Yes

Data from Winsor RE, Falco JE, Dreyer Si, et al. Lumbar discography. *Phys Med Rehabil Clin N Am*. 1995;6:743–770.

worse with lumbar flexion and unsupported sitting, as intradiscal pressures have been found to be higher in these positions (176). Physical examination should reveal a normal neurologic examination if the discogenic pathology does not affect the nerve roots.

### Radiographic Correlation

MRI and CT of the lumbar spine can be useful initial assessment tools because they are noninvasive tests that allow for visualization of multiple discs. Although they have high sensitivity (Figs. 68-18 and 68-19) for detecting anatomic disc abnormalities, surgically proven internal disc disruption has been reported in cases of normal-appearing MRIs (177). MRI carries a high rate of false-positive findings, as shown in studies of asymptomatic patients (178). In addition, they cannot provide the physiologic information about whether an abnormal-appearing disc is actually a pain generator. Although high-intensity signal zones (HIZ) in the posterior annulus on MRI have been linked to discogenic pain (Fig. 68-19), the HIZ can also occur in asymptomatic patients (179–182). With no pathognomonic features of discogenic pain and a high false-positive rate of anatomic findings on noninvasive diagnostic tests, the diagnosis of symptomatic lumbar disc diseases requires a physiologic study for better clinical correlation of a patient's pain with CT or MRI abnormalities. Provocation discography is a physiologic test for discogenic pain.

### Anatomy and Pathophysiology of Discogenic Pain

The intervertebral disc is a well-innervated structure with A-delta and C-pain fibers (183) containing nociceptive substances such as substance P, calcitonin gene-related product,

**FIGURE 68-18.** Lateral plain film nucleography demonstrating a posterior annular fissure in the L4-5 and L5-S1 discs, respectively, through which contrast leaked into the ventral epidural space. Compare this image with that in Figure 68-23. The nucleography of the L3-4 discs was normal. The patient had concordant back pain at the L4-5 and L5-1 discs but no pain at the L3-4 discs.

**FIGURE 68-19.** T2-weighted sagittal images of lumbar spine. MRI demonstrating degenerative disc disease, especially at L5-S1.

VIPs in the annulus fibrosis (184–186). Nerve growth factor has been found in both the annulus fibrosis and nucleus pulposus, which may increase pain sensitization (187). In healthy intervertebral discs, only the outer one third of the annulus fibrosis is innervated. Study of intraoperative samples from degenerative intervertebral discs of patients with chronic back pain demonstrated evidence of inward growth of nerve fibers along the radial fissures into the inner annulus (185,186). The presence of the neural structures and nociceptive fibers is believed to be the anatomic basis of chronic low back pain due to degenerative disc diseases. Discogenic pain may occur in internal disc disruption, which is a condition characterized by a degraded nucleus pulposus with radial fissures extending into the peripheral annulus fibrosis (Fig. 68-19) (188,189). The outer margin of the annulus is intact. The nucleus pulposus, reaching the innervated outer annulus through the annular fissures, invokes an intensive local inflammatory process. These inflammatory substances irritate and sensitize the nociceptive fibers in the outer annulus. The threshold for nociceptive mechanical stimulation is lowered in these chemically sensitized nociceptors. Chronic discogenic pain may result from mechanical stimulation of sensitized nociceptors with normal lumbar disc loading. In fact, intraoperative mechanical stimulation of the posterior annulus in the presumed painful segment induced low back pain in one study (190). Degenerative disc disease is believed to account for some 40% of patients with chronic low back pain of unclear origin (191).

### Indications

Indications for discography appear in the “Position Statement on Discography” from 1988 and 1996 by the Executive Committee of the North American Spine Society (192):

- Patients with unremitting spinal pain of greater than 4 months and unresponsive to all appropriate methods of conservative therapy

- Patients in whom other investigations have failed to explain the source of pain
- Chronic back pain patients who are contemplating intradiscal or surgical procedures such as spinal fusion

### Technique

Discography is generally performed in a radiologic suite or an operating room. The patient is placed in either a prone or oblique side-lying position. A pillow is placed under the patient's abdomen to reverse lumbar lordosis. The lumbosacral area is prepared and draped in a sterile fashion. The patient's vital signs should be monitored and oxygen saturation recorded with a pulse oximeter. A peripheral intravenous line should be established for light conscious sedation.

An AP fluoroscopic view is then used to identify the appropriate disc level. The fluoroscope is tilted in either a cephalad or caudad direction to best visualize the target disc space on radiograph. The C-arm is then rotated ipsilaterally to place the superior articular process of the subjacent vertebral body in a position that bisects the vertebral body above. An appropriate size spinal needle, typically a 25-gauge, 3.5-in. spinal needle is used to infiltrate the skin and subcutaneous tissue down to the superior articular process with 1% lidocaine. Caution should be exercised not to inject local anesthetic overzealously in the superior articular process area in order to avoid potential spread to the epidural or nerve root areas, thus compromising the patient's ability to perceive pain during the subsequent provocative discography. To reduce the chance of discitis, a two-needle technique with 18- or 20-gauge, 3.5-in. introducers and 22- or 25-gauge, 6-in. inner needles, is recommended. The introducer needle is inserted and directed to the outer edge of the superior articular process in the AP view and just to the anterior border of the superior articular process in the lateral view. The inner needle is then inserted through the introducer and slowly advanced to the center of the nucleus pulposus using alternating AP and lateral views. If the patient complains of radicular pain or paresthesias in a nerve root distribution during needle advancement, the needle should be withdrawn and redirected. If a pressure-controlled system is used for the injection, the needle is connected to an injection system with a manometer that is filled with nonionic and water-soluble contrast. The injectionist then injects contrast slowly, monitoring the pressure reading and the patient's reports of pain simultaneously. The opening pressure is the pressure reading at the first appearance of dye in the disc on fluoroscopy. The endpoint of the injection occurs when the patient reports concordant pain (defined as reproduction of pain in the same location and intensity), or when 2 mL of total volume is injected into the disc or the pressure reading reaches 90 lb per square inch (psi). To help minimize the chance of discitis, 5 to 10 mg of cefazolin can be injected into each disc before needle removal. One level above and below the disc with concordant pain should be also studied so as to serve as a control (Figs. 68-20 to 68-22).

Information obtained from discography includes the volume of contrast injected, the patient's pain response (no pain,

**FIGURE 68-20.** Sagittal T2-weighted lumbar spine MRI demonstrating degenerative disc disease at L5-S1 and possible degenerative disc disease at L4-5 and L3-4.

dissimilar or discordant pain, similar pain, and exact pain provocation or concordant pain), degree of resistance to injection, morphology of the nucleogram, and postdiscogram CT morphology of the disc (193).

Postinjection CT scanning provides an axial view of the injected discs (Fig. 68-23). Patterns of radial and concentric annular fissures are more clearly defined in this plane. Postdiscography CT scanning should be performed within 2 hours of the discogram to prevent diffusion of dye out of the nucleus. The Dallas Discogram Description, in addition to recording the pain and contrast volume injected, describes morphologic degrees of annular degeneration and disruption (194). Annular degeneration and disruption are graded by the percentage of the contrast injected that fills the annulus and annular fissures toward the outer annulus as revealed by the

**FIGURE 68-21.** Lateral view of lumbar discograms reveals a posterior annular fissure at L4-5 and L5-S1 discs. The discography reproduced the patient's clinical symptoms (concordant) at L4-5 and L5-S1 discs but no pain at L3-4 discs.

**FIGURE 68-22.** AP view of lumbar discograms demonstrated left side posterior annular fissures.

contrast (Table 68-8) (195). A study by Derby et al. found that there was a significant correlation between the extent of annular disruption on CT and the rate of symptomatic disc on discography, with significant differences between grade 3 and 5 versus grade 0 and 2 (196).

A positive discogram requires a concordant pain response, an abnormal nucleogram, and a normal control level. In contrast, multilevel painful discs without a normal control disc on injection are unexplainable and cannot be regarded as positive.

### Validity of Discography

In a prospective and controlled study in 1990, by applying modern manometry and postdiscography CT technology, refined needle placement techniques, less irritating contrast dye, stressing concordant pain, or discordant pain in addition to disc morphology (195), Walsh concluded that using

**FIGURE 68-23.** Lumbar postdiscography CT image demonstrating the track of contrast that leaked through a radial fissure into a circumferential outer annular fissure.

**TABLE 68.8** Grading of Annular Degeneration and Annular Disruption

Grade	Annular Degeneration	Annular Disruption
0	No change	None (i.e., no contrast extension)
1	Local (contrast fills <10% of the annulus)	Into inner annulus
2	Partial (contrast fills <50% of the annulus)	Into outer annulus
3	Total (contrast fills >50% of the annulus)	Beyond outer annulus

Data from Sachs. BL, Vanharanta H, Spivey MA, et al. Dallas discogram description. A new classification of CT/discography in lowback disorders. *Spine*. 1987;12(3): 287–294.

stringent criteria, the false-positive rate of lumbar discography in asymptomatic individuals is 0% and the true-positive rate in symptomatic patients is 89% (189). However, Walsh's study is limited by its small sample size (i.e., only ten controls and seven patients).

In a retrospective study, Derby et al. reported that a patient with a chemically sensitive disc, defined as one having a concordant pain response provoked with intradisc pressure of less than 15 psi as measured by a manometer, has a better outcome with interbody fusion versus intertransverse fusion surgery (197). This better surgical outcome presumably resulted from the removal of the mechanical load or stimulation to the chemically sensitive disc through removal of the painful intervertebral discs and stabilization with interbody fusion (197). Nevertheless, these investigators pointed out that discography should never stand alone as a diagnostic tool and sole factor for a clinical decision. The presence of a chemically sensitive disc does not rule out other coexisting sources of pain, nor does it exclude patients with excessive pain magnification. Discography should be used in conjunction with other diagnostic tests, such as MRI and CT scans, as well as the patient's history, physical examination findings, response to a comprehensive therapeutic program, and psychometric profile information. Therefore, careful candidate selection is the key to maximizing clinically valuable data from discography. A recent study by Carragee et al. in 2000, although controversial, revealed a high false-positive rate with lumbar discography in a mixed population of 26 asymptomatic patients (182). A significant positive pain response and pain-related behavior with discography were found in 10% of the pain-free group and in 83% of the somatization disorder group. Discs with annular disruption were more likely to be painful on injection. The study concluded that if strict criteria are applied, the rate of false-positive discography may be low in subjects with normal psychometric profiles. Schwarzer et al. in 1995 (183) reported that a discogram is likely to provide highly specific information on the painful lumbar disc when the following characteristics are present: (a) unremitting low back pain persisting after 6 months of conservative care;

(b) no prominent psychological dysfunction; (c) injection of all degenerated discs and one normal disc by MRI; or (d) combination of the results of appropriately and carefully performed provocative and imaging tests.

### Complications of Discography

Potential complications of discography include discitis (0.05% to 4%), nerve root injury, subarachnoid puncture, chemical meningitis, bleeding, and allergic reaction (192). Use of sterile technique, a two-needle technique, as well as intradiscal antibiotics, can reduce the risk for infection (198).

## SUMMARY

In addition to providing imaging of disc morphology, discography is the only provocative physiologic test that can provide information on whether a degenerative disc is the source of pain. In appropriately selected patients, discography is a safe, reproducible, objective diagnostic tool when testing includes volume, pressure, fluoroscopic abnormalities, and pain provocation. Discography results help guide surgical management of chronic back pain. A negative discogram or a multilevel positive discogram without a painless control level can help to exclude a patient as a surgical candidate. Conversely, a single- or double-level positive discogram, along with other clinical data, can help to guide operative planning with respect to fusion or other surgical procedures. This potentially optimizes surgical outcomes. Whether diagnostic discography will actually change surgical outcome depends on many factors, such as a patient's psychosocial factors, job situation, and the surgical technique employed. The true value of diagnostic discography will likely remain controversial until a prospective, randomized, double-blind, and controlled clinical trial on the outcomes of surgery based on discography is carried out.

## COCCYX INJECTIONS

Coccyx pain (coccydynia) apparently occurs far less commonly than lumbosacral pain. Coccydynia can be a severe and persistent pain, causing significant suffering, frustration, and functional limitations (199). These patients often have a history of coccyx trauma (e.g., from a fall or childbirth) resulting in contusions, fractures, dislocations, or other injuries. However, other cases are idiopathic. Typical symptoms include focal tailbone pain, particularly worse with sitting and sometimes immediately worse upon going from sit-to-stand (199). Careful screening should seek to exclude malignancies of the spine (e.g., chordoma) and intrapelvic structures (e.g., rectum) (199,200). Useful diagnostic studies may include x-rays, MRI, CT scans, and colonoscopy (199). Dynamic radiographs comparing coccygeal alignment and angulation while sitting (weight bearing on the coccyx) versus standing may reveal dynamic instability (dislocations) not visualized via non—weight-bearing studies (201,202).

Injections for coccyx pain may include focal corticosteroids placed at the posterior coccyx or into a sacrococcygeal or coccygeal joint, ideally performed under fluoroscopic guidance to maximize injection accuracy and minimize the risk for inadvertent puncture of the rectum or other nearby structures. Diagnostic nerve blocks can include local anesthetic blockade of the somatic posterior coccygeal nerve fibers as well as the sympathetic nerve fibers (ganglion Impar) anterior to the coccyx (203–207). For both diagnostic and therapeutic injections, it is frequently helpful to simultaneously block both the anterior (sympathetic) and posterior (somatic) nerves. This combination can more completely shut off all afferent inputs from the coccyx, with resultant relief implying that the coccyx is the source of pain. Also, effective local anesthetic blockade can provide therapeutic benefit, sometimes including complete and permanent relief (208). The mechanism is perhaps via disrupting hyperactive and/or hypersensitive afferent reflex arcs or sympathetically maintained pain. The various technical approaches to the ganglion Impar include injecting a spinal needle from inferior to the coccyx (above the anus), or passing the needle through the sacrococcygeal joint or through the intracoccygeal joints (203–207). Fluoroscopic guidance is crucial for safe and effective performance of sympathetic nerve blocks at the ganglion Impar, especially given the close proximity to the bacteria-laden rectum. Nerve ablation in the coccyx region may be beneficial for selected patients with coccydynia (207). Most patients with tailbone pain will obtain adequate relief via nonsurgical treatments such as injections, thus often avoiding the need for surgery and its potential complications (209).

## CHAPTER CONCLUSIONS

In selected patients, spinal injections can offer diagnostic and therapeutic benefits. Spinal injection procedures have become an important part of clinical armamentarium for the musculoskeletal physiatrist. Efforts should be directed toward selecting appropriate patients and incorporating injection procedures into an overall rehabilitation program to relieve pain, maximize function, and improve quality of life.

# Palliative Care Symptom Management

## INTRODUCTION

Palliative care involves a holistic approach to comprehensive symptom management. This represents a significant departure from the emphasis on disease-modifying treatment that dominates allopathic medicine. The specialty originally developed as a body of medical expertise geared toward the care of dying patients. Its roots are intertwined with those of the hospice movement. Unfortunately, the equation of palliative care with hospice medicine persists to the field's detriment. This limited view fails to recognize that palliative care principles can be applied to alleviate symptoms and enhance quality of life (QOL) in many stage of illness, not solely the terminal.

Palliative care specialists have advocated a parallel model of care delivery with integrated use of disease-modifying and symptom-oriented therapies across disease continua. This model proposes that palliative care be provided from the time of diagnosis onward with emphasis appropriate to patients' symptom burden irrespective of their prognoses. As suggested by the schematic of this model presented in Figure 69-1, palliative care plays an increasing role with disease progression, and symptom control ultimately becomes the sole agenda at the end of life. This approach is based on the belief that palliative care has a role in the management of all disease states associated with an intense and adverse symptom complex.

## Origins

Before the advent of the modern medical era, interventions were largely palliative given the limitations of disease-modifying treatment. Comfort-oriented care was integral to medical management, frequently representing practitioners' sole option. Physicians' reliance on skillful symptom control informed medical education, research, and discourse. A steady shift in emphasis away from this symptom-oriented approach began with the integration of antibiotics into mainstream care as these were among the first dramatically effective disease-modifying agents in widespread use. Although simultaneous medical advances occurred, none paralleled the dramatically improved outcomes afforded by antimicrobials. Growing interest in disease mechanisms led to a marked expansion in pathophysiological research and consequent refinement of our understanding of responsible agents and mechanisms. Elucidation of disease processes opened the door for generations of "rational" medical therapies. A path was forged from the lab bench to the bedside, and the medical establishment

became heavily invested in scientifically driven disease modification.

The success of scientifically driven disease modification is unequivocal. However, its achievements have not come without casualties. Expertise and interest in symptom control waned with medicine's focus on disease-targeted interventions. In the early 1960s, clinicians began to recognize that dying patients or those whose diseases failed to adequately respond to therapy were being marginalized and suffering as a consequence. Clinician avoidance of dying patients has been well documented (1–3). In an effort to more sensitively and consistently care for the dying, the hospice movement was born. From humble origins, hospice care expanded and is now globally embraced. With the growth of care delivery models for patients with terminal illnesses came a demand for empiric research in symptom management, greater physician expertise, and empirically derived treatment algorithms. Palliative care represents the response to these demands.

## Relevance to Physical Medicine and Rehabilitation

Enhanced disease-modifying therapies are allowing patients to survive longer in the advanced stages of many diseases. This trend has characterized the treatment of acquired immunodeficiency syndrome (AIDS) and many cancers. Although life may be extended, these patients are not spared functional decline (3). Progressive debility and dependence are increasingly leading these patient populations to seek psychiatric attention. Multiple surveys have demonstrated that patients with advanced disease strongly desire functional autonomy and are deeply concerned over the prospect of becoming an increasing caretaker burden (4–6). It is critical that physiatrists rise to the challenge of providing expert and effective functional restoration within the confines imposed by their diseases. The fiscal, emotional, and social burden of unmitigated impairment is extremely high (7–9). Studies suggest that rehabilitative interventions can successfully restore function even in hospice-bound patients and those with widespread metastatic disease (10,11).

To date, little interface has occurred between rehabilitation medicine and palliative care. This is an unfortunate circumstance for both fields, particularly for the many patients with advanced disease who stand to benefit from the fields' complementary skill sets of symptom control and functional restoration. Symptoms must be adequately controlled if patients are to participate fully

**FIGURE 69-1.** Proposed model of palliative care delivery in which symptom-oriented care is concurrently administered from the time of diagnosis. As disease progresses, increasing emphasis is placed on palliative care.

and benefit from rehabilitation. Without physiatric expertise, patients are unable to translate their enhanced comfort into self-directed activities, social integration, and improved QOL.

## Chapter Overview

The majority of this chapter discusses the most prevalent adverse symptoms in patients with advanced disease. Palliative care is, in essence, expert, multimodal symptom control in refractory disease states. The pathophysiology, causes, and treatment of each symptom or clinical problem are addressed. The second, briefer, portion of this chapter outlines exercise as palliation and describes current, integrated palliative care delivery models. Both parts of the chapter have a common goal of imparting a body of knowledge geared toward the preservation of dignity and autonomy in symptomatic patients with progressive illnesses.

## SYMPTOM ASSESSMENT

A uniform approach to symptom assessment will maximize the chances of appropriate diagnosis and treatment. Assessment of all symptoms should be conducted in a rigorous and structured fashion. Most symptoms can be caused by a range of etiologies, some of which may be amenable to definitive, disease-modifying treatment. For example, pain from discrete bone metastases is best managed with focal irradiation. Effective treatment requires identification of all contributing factors. Assessment should be conducted with the awareness that symptoms are dynamic processes that vary in intensity, quality, frequency, and level of associated distress (12). For some symptoms, reliable assessment instruments have been developed and validated. Table 69-1 lists commonly used instruments.

A critical dimension of palliative care, distinct from other fields of medicine, is the overriding emphasis on patients' subjective experience. Subjective distress and discomfort displace disease processes as the primary therapeutic targets.

Observer ratings of symptom severity, both those of caregivers and clinicians, correlate poorly with patient ratings and are generally an inadequate substitute for patient reporting (13–16). Therefore, the presence and the severity of symptoms must be accepted at each patient's word.

An approach that has been widely endorsed for the comprehensive assessment of pain can be readily applied for the assessment of any symptom (17–19).

1. Query patients about the intensity of their symptom "on average, at worst, and at best." Intensity ratings can be provided with 6- or 11-point linear analogue self-assessment (LASA) or numeric rating scales anchored at either end by "no symptom" and "symptom as bad as it can be." Alternatives to numeric ratings, including faces and color indicators, have been validated for use in children and cognitively impaired adults (20).
2. Clarify the symptom's temporal profile. "How frequently does your symptom (pain, fatigue, nausea, etc.) reach its worst level, for example, 9/10?" "On a normal day, how long is your symptom at its best level, for example, 2/10?"
3. Inquire about exacerbating and remitting factors. "What causes your symptom to reach its worst and best levels?" Examples of activities (e.g., transfers, eating) and body positions (e.g., sustained standing, side lying) can be offered to patients.
4. Invite the patients to qualitatively describe their symptom. "Can you tell me what your pain feels like?" Qualitative descriptors may hold important information about a symptom's pathophysiology with treatment implications. For example, the distinction between nociceptive and neuropathic pain may be essential to successful management.
5. Characterize the degree to which the symptom interferes with function, mood, sleep, social interactions, etc. LASA or Likert scales can be utilized for this purpose. More consistent and structured evaluations may be achieved by asking patients about symptom interference with specific activities of daily living (ADLs) and instrumental ADLs.
6. Establish whether any related symptoms or signs are undermining the patient's comfort and function. For example, the presence of neurological deficits, focal edema, or autonomic deficits that parallel a symptom's time course suggests a critical need for imaging.

Semantics may interfere with reliable symptom reporting. The terms *nausea*, *pain*, *anxiety*, and *fatigue* vary in significance and import to different patients (21). For example, some patients use the term *nausea* to describe abdominal discomfort, pain, distention, or early satiety. Soliciting multiple qualitative descriptors helps to clarify the precise characteristics of the symptom being evaluated. For many symptoms, the extent of physiologic and anatomic disturbance does not correlate directly with symptom intensity. Symptoms can augment one another when they occur in clusters (22–24). Interactions among symptoms should be explored to clarify the degree to which each symptom, or its treatment, induces or exacerbates other physical or psychological symptoms. Evaluation should attempt to distinguish whether

symptoms are (a) concurrent but unrelated in clinical etiology, (b) concurrent and related to the same pathological process, (c) concurrent with one symptom directly or indirectly consequent to a pathologic process initiated by the other symptom, or (d) concurrent with one symptom consequent to therapy directed against the other. These distinctions are challenging, but critical for successful comprehensive management.

Obtaining a detailed history with special emphasis on patients' medication histories is fundamental to symptom management. Medications are an extremely prevalent source of adverse symptoms. Patients may be taking multiple medications for primary disease modification, symptom control, prophylaxis against complications, and medical comorbidities. Interactions between these medications must be considered. A medication can indirectly influence a symptom by reducing the protein binding or slowing the metabolism of medication(s) directly responsible for the symptom. Comorbid medical conditions should also be carefully reviewed. Diabetes, chronic renal insufficiency, autoimmune disorders, hepatic failure, peripheral vascular disease, among many other common diseases, can both influence adverse symptoms and be influenced by them. Too often, clinical attention becomes exclusively focused on the primary disease process, leading to neglect of other potentially important pathologic contributors.

Appropriate imaging and serologic evaluations will vary contingent on the symptom being evaluated and the clinical context in which it occurs. The choice of appropriate diagnostic tests should be guided by the stage of disease, the prognosis, the risk/benefit ratio of any proposed test or intervention, and the desires of the patient and the family. Evaluations that are associated with significant discomfort, risk, or expense, or that demand an extended time commitment must be weighed in light of the extent to which clinical management will be meaningfully altered.

The introduction of item response theory (IRT)-based instruments into the mainstream is a recent development in

symptom assessment that is likely to have far-reaching influence on both clinical and research endeavors (25–29). Given the emphasis that the National Institutes of Health and preeminent psychometricians have placed on IRT-based assessment, readers will be well served by some familiarity with these concepts. Simply put, IRT represents an alternative to classical test theory, which maintains that symptom assessment tools must be administered as fixed-length instruments in their entirety without varying item order or presentation to remain valid. In contrast, IRT asserts that individual items, not multi-item instruments, are the foundation of accurate assessment and that reordering items or utilizing subsets of items does not compromise validity (30). IRT-based methods allow clinicians and researchers to select limited numbers of items from much larger item pools in order to match the sensitivity of the selected items with the symptom intensity of their population of interest (31). For example, items (e.g., “My pain is so bad that I can't breathe: Always, Often, Sometimes, etc.”) that are sensitive to the intense pain experienced by cancer patients may be uninformative when administered to patients with relative mild pain related to tendonopathy. More comprehensive and intelligible descriptions of IRT, Rasch modeling, and computer adaptive testing are widely available. Interested readers are encouraged to explore the following resources: *Item Response Theory: Principles and Applications* by Hambleton and Swaminathan and *Health Status Assessment for the Twenty-First Century: Item Response Theory, Item Banking and Computer Adaptive Testing* by Revicki and Cella in Quality of Life Research, 2004.

## PAIN

Pain becomes a disturbing reality for a majority of patients at some time over the course of progressive illness, particularly those with cancer and AIDS. The degrading impact of

uncontrolled pain on functional autonomy and QOL has been well documented (32). Adequate pain control is essential if QOL and functional autonomy are to be preserved.

## Epidemiology

Pain epidemiology has been most extensively studied in cancer cohorts with reported prevalences ranging from 14% to 100% (33), with prevalences of 50% to 70% being noted in patients receiving active treatment (34). Prevalence rates increase to 60% to 90% near the end of life (35). Between 36% and more than 50% of ambulatory cancer patients report pain severe enough to significantly impede function (36). Inadequate pain management has been well documented, with as many as 40% of ambulatory cancer patients receiving insufficient analgesia according to World Health Organization (WHO) standards (36). In one report, 82% of patients with advanced cancer admitted to hospice were undermedicated and in significant pain (37). Patients who are female, of minority status, or former substance abusers are at highest risk for undertreatment (36). The prevalence of uncontrolled pain is alarming, given that the combined use of pharmacologic and interventional analgesic approaches is able to control 90% of severe cancer pain (38). However, it is worth noting that estimates of cancer pain undertreatment derive from research published in 1993 and may not accurately reflect current rates or predisposing characteristics.

## Causes

Pain in the setting of advanced illness often arises simultaneously from multiple sources. This is particularly true in the context of disease progression, which may create significant diagnostic and therapeutic uncertainty. An organizational structure facilitating characterization of most disease-related pain syndromes has been proposed that involves characterizing the pain's precipitant (e.g., disease- or treatment-related) and presumed pathophysiology (e.g., nociceptive somatic, nociceptive visceral, or neuropathic) (39). This rubric has been most consistently applied to patients with cancer-related pain. Table 69-2 lists common cancer pain syndromes and places them within this organizational framework. The distinction between nociceptive and neuropathic pain pathophysiology has

both prognostic and therapeutic significance (40). Nociceptive pain responds extremely well to disease-modifying and opioid-based therapies. Neuropathic pain is pain that arises through deranged functioning of the nervous system (40). Neuropathic pain frequently proves more refractory to treatment than nociceptive pain but may respond to adjuvant analgesics.

Pain generators have been extensively described for cancer patients. Direct tumor effects on bone, nerve, soft tissue, or viscera account for 65% to 75% of pain (41–43). Anticancer therapies are responsible for 15% to 25% of cancer-related pain (41–43). Pain syndromes may develop following surgery (e.g., postthoracotomy pain), radiation therapy (e.g., osteoradionecrosis), or chemotherapy (e.g., peripheral neuropathy). Five to ten percent of patients report pain unrelated to their cancer or its therapy (41–43). Patients with AIDS, far-advanced arthritides, and severe vasculopathies frequently experience intense pain characteristic of these syndromes.

## Treatment

A wide array of analgesic strategies is currently available. Pain management approaches commonly used in advanced cancer are listed in Table 69-3. Opioid-based pharmacotherapy is the preferred strategy for managing cancer pain. This approach has been generalized to the treatment of pain arising from other terminal conditions on the basis of theoretical rather than empiric grounds. The widespread success of this approach in controlling cancer pain has led to strong endorsement by numerous international and national organizations, as well as a federal task force (44–47). Countless chapters, books, and review articles published over the past decades have advocated the skillful integration of disease-modifying therapy with the use of opioid and nonopioid analgesics.

Disease-modifying therapy is the treatment of choice, irrespective of etiology, because it may permit definitive, lasting pain relief. For cancer patients, disease-modifying treatments are geared toward reduction or eradication of tumor. Therapies may include surgery, chemotherapy, radiation therapy, and the delivery of radiopharmaceuticals. The reduction of tumor effects on normal tissue may reduce or eliminate pain. Despite the widespread practice of delivering chemotherapy to address cancer pain, the analgesic benefits of this

approach remain unproven and pain alleviation in the absence of tumor shrinkage has been documented (48,49). Treatments targeting primary, noncancer, disease processes (e.g., antibiotics for infections) may offer effective pain control. Such interventions, offering emphatic symptom resolution, may obviate the need for further pharmacologic or interventional therapies.

Strong empirical data establish analgesic pharmacotherapy as the mainstay of cancer pain management (40). Analgesics used for the management of pain associated with advanced disease are broadly grouped into three classes: nonopioid, adjuvant, and opioid. The WHO's analgesic ladder for cancer pain management (Fig. 69-2) advocates combining agents from these different classes in order to capitalize on their different mechanisms of action (50). Clinical application of the WHO algorithm has been shown to control 80% to 90% of cancer pain although its superiority has yet to be established in a randomized, controlled clinical trial (42,51). The indications, benefits, and limitations of agents in each class are discussed as follows.

Aspirin and other salicylates, acetaminophen, and nonsteroidal anti-inflammatory drugs (NSAIDs) constitute nonopioid analgesics. The WHO ladder advocates the use of nonopioids as first-line therapy for "mild" cancer pain. The safety and efficacy of NSAIDs as monotherapy in mitigating pain arising from many etiologies has been well documented (52). Additionally, like acetaminophen, NSAIDs have opioid-sparing effects that may avoid dose-limiting opioid side effects (53). Bone pain from lytic metastases is, in part, prostaglandin-mediated and therefore responsive to NSAID therapy (54).

**FIGURE 69-2.** The World Health Organization Analgesic Ladder.

Unless contraindicated, patients should undergo serial nonopioid trials, particularly those with pain related to osseous metastases or inflammation. The maximal effective dose and degree of patient responsiveness varies considerably among NSAIDs (39). Therefore, sequential trials may be needed to identify the optimal agent and dose. NSAID-related gastropathy and antiplatelet effects in thrombocytopenic patients are a significant concern. Adverse consequences may be reduced through the use of cyclooxygenase-2-selective inhibitors or gastroprotective agents (55). Care must be taken in patients with advanced illness to monitor for hepato- and nephrotoxicity related to acetaminophen and NSAID use, respectively (40).

Adjuvant analgesics, also referred to as *coanalgesics*, comprise a large class of drugs with the capacity to offer pain relief in certain conditions. A majority of adjuvant analgesic trials have been conducted in patients with chronic neuropathic pain (e.g., postherpetic neuralgia). Their efficacy in this setting has served as justification for their use in pain arising from terminal disease states. The appropriateness of this strategy is attested by the inclusion of adjuvant analgesics as an integral part of all current guidelines (50,56–58). Adjuvant analgesics' role as the preferred agents for control of neuropathic pain is supported by numerous clinical trials and literature reviews (59,60). The majority of adjuvant analgesics used to treat pain in advanced disease can be classed as antidepressants, anticonvulsants, or oral local anesthetics. However, the successful use of corticosteroids, antispasmodics, neuroleptics, and osteoclast inhibitors has been anecdotally described, and some agents have been found effective in controlled trials. The most frequently used agents are discussed below.

The tricyclic antidepressants have been most extensively studied among the adjuvants and have well-documented efficacy (61). Secondary amines (e.g., nortriptyline and desipramine) may offer less analgesia relative to tertiary amines (e.g., amitriptyline and imipramine), but have fewer associated anticholinergic side effects (61,62). Selective serotonin reuptake inhibitors have produced poor to mixed results in clinical trials. If cotreatment of depression is desired, the serotonin norepinephrine reuptake inhibitor duloxetine may be a superior choice, although its efficacy for cancer pain remains untested (63).

Trials have established the anticonvulsant carbamazepine as a first-line agent for intermittent lancinating pain. However, the associated risk of causing leukopenia limits its use in patients at risk for hematological abnormalities (64). Both gabapentin and pregabalin produce good results in the treatment of lancinating continuous neuropathic pain (65–68). Their benign side-effect profiles and the lack of drug-drug interactions make them reasonable first- or second-line choice for adjuvant analgesic therapy. Oxcarbazepine, levoteracitam, and lamotrigine may be trialed on theoretical grounds as their utility in controlling pain associated with terminal illness lacks empirical support (40).

Topical agents such as 2% to 4% viscous lidocaine may alleviate pain from mucosal lesions. The degree of analgesia afforded by dermally applied topical preparations is unclear. In a recent blinded, controlled trial, lidocaine-impregnated patches offered no greater relief than placebo for postincisional neuropathic pain in cancer patients (69). A variety of topical salves combining various agents including amitriptyline, ketamine, gabapentin, etc. have been anecdotally endorsed, but empirical evidence is limited and their costs are often prohibitive (70,71).

In addition to NSAID therapy, several adjuvant analgesics are uniquely beneficial in the management of pain arising from bone metastases. These include steroids, bisphosphonates, and radiopharmaceuticals. Dexamethasone is the steroid of choice at doses ranging from 1 mg twice daily to 100 mg daily, with standard doses being 16 to 24 mg/d (40,72). Bisphosphonates inhibit osteoclast activity and effectively alleviate pain from bone lesions (73). Single doses of the radiopharmaceuticals, strontium-89 and samarium, may lastingly alleviate pain arising from diffuse bone metastases as demonstrated in breast and prostate cancer cohorts (74,75).

An extensive international literature describes the control of cancer pain through the use of high-dose, long-term opioid therapy. Recommendations that doses be increased to “effect or side effect” stem from the lack of a therapeutic ceiling for opioid analgesia, although large dose increments may be required at high dose ranges to achieve incremental benefit. Many patients require doses as high as or higher than the equivalent of 5 g of oral morphine per day (76,77). Clinical success and an ever-growing literature has given rise to increased acceptance and comfort with high-dose opioid-based analgesia (76,77).

Opioids can be subclassified as pure agonists (e.g., morphine, oxycodone), agonist-antagonists (e.g., nalbuphine,

pentazocine), and partial agonists (e.g., buprenorphine) based on their interaction with endogenous opioid receptors. With few exceptions, only pure  $\mu$  agonists (e.g., morphine, methadone, oxycodone, hydromorphone, fentanyl) should be used to manage pain in patients with advanced diseases. Physiologic withdrawal syndromes may be precipitated by the use of agonist-antagonists in patients who are physically dependent on opioids (78).

Administration of  $\mu$ -receptor agonists has become increasingly refined over the past decades as new synthetic formulations and routes of administration have become available. Irrespective of these advances, general clinical practices have not been significantly altered (79). Algorithms described in numerous guidelines, chapters, and review articles endorse the following steps:

1. Establish opioid analgesic requirements in “naïve” patients with liberal, as-needed dosing of an immediate-release (IR) (also referred to as *normal-release*) formulation.
2. Once patients’ use of the IR formulation has stabilized, generally after a 1 to 2 week interval, their total daily IR consumption is converted to an equivalent total daily dose of a sustained-release (SR) opioid preparation. When possible, the same IR and SR opioid should be used. Long-acting or SR formulations are generally IR opioids placed in time-release matrices so that they may be dosed at longer intervals. Methadone may be dosed on a schedule of every 8 or 12 hours and therefore may be included among the SR or long-acting opioids (80).
3. Patients’ SR preparations should be supplemented with “rescue” or demand IR doses, typically 5% to 15% of the total daily dose, for preemptive use in anticipation of pain or when the SR preparation fails to provide adequate analgesia.

For example, a patient consuming an average of sixteen 10 mg IR oxycodone tablets per day would require twice daily 80 mg SR oxycodone tablets with rescue doses of 8 to 24 mg of IR oxycodone. Subsequent upward titration of the SR opioid to optimal effect is based on the frequency of IR rescue use. For patients with activity-related incident pain and minimal pain at rest (a scenario commonly encountered in patients with painful bone metastases), higher IR rescue doses and lower SR doses may provide superior analgesia and reduce cumulative daily opioid consumption.

The pharmacologic management of pain in patients with advanced disease requires flexibility in both the choice of medication and the dosing strategy. Contingency planning for rapid analgesic escalation should pain abruptly worsen is critical to long-term success. Oral medications offer both ease of administration and upward titration. At the time of the writing of this chapter, morphine and oxycodone are the only pure  $\mu$ -agonists available in both IR and SR oral preparations. Methadone effectively alleviates cancer pain when dosed both “around-the-clock” and as an as-needed rescue medication (81). However, methadone’s erratic pharmacokinetics demand

caution and use by experienced clinicians to avoid inadvertent, delayed toxicity (82). Further, clinicians should be alert to the possibility of QT prolongation and torsades de pointes with daily methadone doses greater than 300 mg (83,84).

The transdermal route benefits patients lacking or expected to lose the capacity for enteral absorption. Fentanyl and buprenorphine patches are currently the only transdermal opioid formulations available in the United States. Data support the use of both transdermal fentanyl (85,86) and buprenorphine (87,88) to control cancer pain, despite the fact that buprenorphine is a partial  $\mu$ -receptor agonist (89). Fentanyl can also be administered transmucosally in the form of a lozenge that has rapid onset and a discrete duration of action making it a good choice for patients experiencing short intervals of severe pain with physical activity.

Parenteral opioid administration offers the capacity for rapid upward titration and accurate establishment of patients' analgesic needs. Parenteral hydromorphone is a potent opioid (7.5 times more potent than parenteral morphine) that can be administered at concentrations of 20 mg/cc making subcutaneous administration feasible. Fentanyl, oxycodone, methadone, and morphine are also available for parenteral administration. Morphine's availability in long- and short-acting tablets, elixir (2, 4 mg/cc, 20 mg/mL), long-acting pellet (deliverable via nasogastric [NG] tube), and parenteral formulations, as well as highly concentrated subcutaneous preparations, allows tremendous dosing versatility. Also morphine is also quite inexpensive.

Opioid-related side effects need not limit upward dose titration (90). Persistent somnolence can be managed with methylphenidate or modafinil after all nonessential centrally acting medications have been discontinued. A reasonable starting dose of methylphenidate is 2.5 mg twice daily (last dose provided no later than 2 p.m.). Typical effective daily doses range from 10 to 40 mg. Common side effects—including nausea, hyperhidrosis, xerostomia, and constipation, among others—can generally be effectively managed and need not limit opioid therapy (90). When optimal opioid side-effect management proves ineffective, opioids should be rotated (40).

### Invasive Techniques

Most patients with advanced disease attain satisfactory relief of pain through approaches that incorporate oral or parenteral analgesic therapy with other noninvasive strategies. Anesthetic and neurosurgical techniques are generally reserved for patients who are unable to achieve a satisfactory balance between analgesia and side effects, or inadequate analgesia despite escalating doses with sequential, strong opioid drug trials (91). Commonly employed regional analgesic techniques include intraspinal (e.g., epidural and intrathecal) opioids and local anesthetics, intraventricular opioids, and regional local anesthetic blockade (92). Neurolysis of the celiac plexus, superior hypogastric nerve plexus, and ganglion impar may afford control of visceral pain (93). Discrete somatic pain arising from malignant invasion or compression can transiently be relieved through peripheral nerve blocks. Temporary peripheral neural blockade is frequently used

diagnostically to clarify the location of a primary pain generator. Neuroablative surgical techniques, including rhizotomy, neurolysis of primary afferent nerves or their ganglia, cordotomy, and C1 midline myelotomy, may be used for refractory syndromes in patients with limited prognoses (94).

## FATIGUE

Fatigue represents a widely prevalent and highly distressing symptom for cancer patients. It is difficult to overestimate its adverse impact on function because fatigue can significantly compromise patients' incentive and ability to comply with psychiatric interventions. Patients describe fatigue as devastating to many life domains, degrading their vocational, familial, and societal roles (95). Patients with cancer rate fatigue as more distressing than any other symptom including pain (96). Fatigue arguably presents the greatest challenge to functional restoration in patients with terminal illness as it constrains patients' ability to engage in rehabilitation and adhere to regimens required for success. Fatigue may become so severe that patients interrupt or abandon disease-modifying treatments (96).

Current understanding of fatigue is largely derived from studies involving patients with cancer. All formal definitions reflect the experience of "cancer-related fatigue," and generalizations to other disease states should be made with awareness of this orientation. The National Consortium of Cancer Centers (NCCN) defines fatigue as "an unusual persistent subjective sense of tiredness related to cancer or cancer treatment that interferes with usual functioning" (97). Diagnosis of "cancer-related fatigue" per the International Classification of Disease (ICD)-10 requires a known tumor and daily persistence of the symptom for  $\geq 2$  weeks plus 6 of the following 11 complaints: diminished energy, increasing need for rest, limb heaviness, diminished ability to concentrate, decreased interest in engaging in normal activities, sleep disorder, inertia, emotional lability due to fatigue, perceived problems with short-term memory, and postexertional malaise exceeding several hours (98).

Although not included in most formal definitions additional, accepted characteristics of "cancer-related fatigue" include disproportionate tiredness relative to patients' exertional level. Additionally, "cancer-related fatigue" is not relieved by rest or sleep and engenders subjective weakness (99–101). Fatigue reduces patients' mental capacity and psychological resilience (102,103). Patients may report reduced motivation, capacity to attend, concentration, and difficulty acquiring new learning (104).

### Epidemiology

The overall prevalence of fatigue is generally greater than 75% (12, p. 75). Among cancer patients who experience fatigue, most surveys report that one half to two thirds describe the symptom as "highly distressing" (124, p. 53). Fatigue occurs most commonly and severely during administration of anticancer therapies, being reported by as many as 99% of patients receiving chemotherapy (105). Over 40% of patients rate their pain as

“severe” or  $\geq 7$  on an 11-point numerical rating scale (106). Fatigue is frequently present at the time of diagnosis, increases throughout treatment, and persists for years after the completion of therapy (104,107). Cancer patients who report fatigue have decreased disease free and overall survival (108).

### Pathophysiology

The processes underlying fatigue remain poorly understood. Biological response modifiers (e.g., cytokines) elaborated by tumors and by the body in response to tumors/treatments have been blamed for fatigue due to well-characterized temporal associations between their administration for therapeutic purposes and the onset of severe fatigue. The fact that tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin-6 are elevated in some patients with chronic fatigue syndrome, and that synthetic antibodies targeting proinflammatory cytokines reduce fatigue in patients with rheumatoid arthritis further implicate biological response modifiers (109–111). However, levels of circulating cytokines do not correlate with fatigue severity (112). Therefore, biological response modifiers have received less attention in current mechanistic discussions.

The role of serotonin(5-HT) dysregulation in fatigue has been studied due to evidence that 5-HT contributes to pathological fatigue states as well as fatigue experienced by healthy subjects during intense exercise. Tryptophan, a precursor of 5-HT, levels increase significantly during normal exercise within the brain (113) and patients with chronic fatigue syndrome have elevated serum tryptophan levels (114). However, central 5-HT concentrations do not correlate with the presence or the intensity of cancer-related fatigue suggesting that 5-HT dysregulation is neither required nor sufficient to engender fatigue (115,116).

Data directly link aberrant hypothalamic-pituitary-adrenal (HPA) axis function to fatigue. Breast cancer survivors with fatigue demonstrate blunted stress responses reflected in low salivary cortisol levels when stressed relative to unaffected controls (117). Investigators speculate that irregularities in diurnal cortisol regulation may be highly relevant to the genesis of pathological fatigue (118). Since cortisol, cytokines, and 5-HT levels regulate one another, HPA axis has been proposed as a unifying mechanism by which cytokines and 5-HT may produce fatigue (104).

Fatigued cancer patients demonstrate abnormal sleep-wake cycles and rest-activity patterns. Diminished daytime physical activity and excessive movement during sleep are associated with fatigue in patients with breast and colorectal cancers (119,120). Fatigued patients with stage IV colorectal cancer, display diminished variation in rest-activity patterns (108,121).

A definitive mechanism that accounts for all pathological fatigue remains elusive and likely reflects its underlying complexity and nonuniform pathogenesis. Different mechanisms may interrelate and dominate in different patients and disease states.

### Causes

Fatigue may relate to myriad factors, both treatment and disease related, which are potentially modifiable. A discrete source of

fatigue can be identified in some patients, leading to symptom alleviation. More often, many potential contributors of unclear relative importance can be identified. Endocrinopathies, blood dyscrasias, degraded sleep quality, centrally acting medications, steroid myopathy, and cachexia represent possible engendering and aggravating factors.

Anemia has received consistent emphasis as a fatigue source since roughly 50% of patients with solid tumors are anemic at diagnosis and many anticancer therapies reduce red blood cell count (122). The relevance of anemia to cancer-related fatigue has diminished with the recognition that the time course of fatigue differs substantially from fluctuations in blood counts. Normalization of hemoglobin levels through blood transfusion or erythropoietin administration fails to consistently alleviate fatigue. No specific reduction or increase in hemoglobin levels has been definitively linked to quantitative changes in QOL or performance status.

Endocrinopathies are underdiagnosed and, in general, easily rectified. Disruption of the adrenal axis, thyroid gland, testes, and ovaries by disease- or treatment-related processes occurs commonly in a range of terminal disease states. Appropriate serologies allow identification of deficiencies.

Centrally acting pharmaceuticals are commonly administered to patients with advanced illness and represent a cornerstone of palliative care. Whenever possible, needless or ineffective sedating medications should be eliminated or replaced by less problematic alternatives. Withdrawal trials may clarify the benefit to side-effect ratio of centrally acting pharmaceuticals in helping patients and clinicians appreciate their utility (103).

### Treatment

Methylphenidate has been extensively used to alleviate fatigue in patients with cancer. Four of seven clinical trials to examine the efficacy of methylphenidate in alleviating fatigue resulted in benefit (123–126). A small pilot study combining exercise and methylphenidate, also (open-label), detected benefit (125). Results from two controlled, double-blinded studies conflict but trial designs differed in maximal doses, trial duration, and inclusion criteria (126,127). Based on current evidence, a trial of methylphenidate is justified for patients with debilitating fatigue starting at a dose of 5 to 10 mg/d. Dose-limiting toxicities associated with methylphenidate include anorexia, insomnia, anxiety, confusion, tremor, and tachycardia.

Modafinil, also a central nervous system (CNS) stimulant, has been studied in two open-label trials. Survivors of breast cancer experienced reduced fatigue, as did patients with brain tumors, while taking modafinil (128,129). Modafinil causes mild, tolerable side effects (e.g., headache, anxiety, nausea) that resolve upon discontinuation. Treatment can be started at 100 to 200 mg/d and titrated to a maximal dose of 400 mg/d.

Antidepressants inconsistently alleviate fatigue in depressed patients with cancer. SR bupropion (100 to 300 mg/d) in two open-label case series alleviated fatigue after two to four weeks

of treatment (130,131). Paroxetine has been more rigorously studied with double-blind, control trials. Two such efforts detected enhanced mood but no change in fatigue (115,116). The effect of serotonin-norepinephrine reuptake inhibitors on fatigue has yet to be examined.

Patients with advanced, metastatic cancer and fatigue experienced benefit from corticosteroids in two randomized, double-blind, crossover studies (132,133). Prednisone also reduced fatigue in a less rigorous open-label study (134). Side effects of sustained steroid use may limit their utility to patients with advanced illnesses.

L-carnitine dosed at 500 to 600 mg/d alleviated fatigue in three small, open-label trials (135–137). All studies enrolled patients with cancer. These promising results have yet to be replicated with a blinded study design.

Exercise may offer the greatest benefit of all fatigue alleviating therapies, though its feasibility has yet to be researched in advanced illness. Aerobic conditioning consistently reduces fatigue in cancer survivors and in patients receiving adjuvant chemotherapy (138–140). No harm has been associated with aerobic exercise at 75% to 80% maximal heart rate. Resistance training has been more limitedly studied, yet the encouraging pattern of reduced fatigue persists (141). Androgen-deprived patients with prostate cancer experienced improved QOL, fatigue, and strength after performing two sets of 8 to 12 repetitions at 60% to 70% of one maximal repetition over a 12-week period (142). Participants in exercise programs have never reported reduced QOL or increased fatigue, irrespective of their intensity.

Increasing evidence supports the efficacy of psychosocial interventions to mitigate fatigue. Many different types of interventions including support groups, psychoeducational nursing interventions (e.g., coping, stress management, problem solving), energy conservation and activity management, psychologist- or self-administered stress management, nurse-administered cognitive behavioral symptom management intervention, and structured psychiatric group intervention have been studied with randomized, controlled study designs (107). Consistent fatigue reduction has been reported across this wide variety of therapeutic approaches. In spite of convincing evidence, programs offering psychosocial treatment are not widely available and patients with advanced illness may actually experience increased fatigue with intensive and demanding programs (143).

## NAUSEA AND VOMITING

### Epidemiology

Chronic nausea and vomiting are prevalent and distressing problems in patients with advanced cancers and other diseases. The reported prevalences vary depending on the clinical population surveyed and the assessment method with reported prevalence rates from 40% to 70% in the palliative care setting (144,145). In a case series conducted by Fainsinger et al. (146), 71 out of 100 patients in a palliative care unit required

treatment for nausea in the last week of life. Uncontrolled nausea and vomiting have the capacity to degrade patients' physical and psychological well-being, seriously undermining their QOL (147). Nausea is more common than vomiting and defined as chronic when it lasts more than 1 week in the absence of clear, self-limiting sources, for example, chemotherapy (148). Control of nausea and vomiting can provide patients with a sense of control over their body and life, decrease anxiety and fear, decrease caregiver burden, and better enable patients to autonomously perform ADLs.

### Pathophysiology

Much of our understanding of the pathophysiology of nausea and vomiting derives from research on patients receiving chemotherapy and radiation therapy. It is critical that a distinction be made between nausea and vomiting. Nausea is a subjective symptom involving an unpleasant sensation experienced in the back of the throat and epigastrium that may not result in vomiting (149,150). Vomiting, in contrast, is the reflexive elimination of gastric contents through forceful contraction of abdominal muscles to expel toxic substances. The mechanisms underlying vomiting are far better understood than those responsible for nausea.

Distinct sites in the brain, namely the vomiting center (VC) and the chemoreceptor trigger zone (CTZ), are responsible for control of vomiting (151). The VC is an interrelated neuronal network in the medulla including the nucleus tractus solitarius and the dorsal motor nucleus of the vagus. Projections to the VC arise from peripheral pathways, the vestibular system, and the CTZ located in the area postrema of the medulla, as illustrated in Figure 69-3 (152). The CTZ lies outside the blood brain barrier enabling it to sample toxins and metabolic abnormalities. The CTZ responds to chemotherapeutic agents, metabolic products, opioid, and bacterial toxins with stimulation of the VC resulting in emesis. Vomiting induced by raised intracranial pressure, taste, smell, and anxiety is mediated through afferent VC projections from the cortex, diencephalon, and limbic system (153). Projections from the vestibular center participate in motion-induced nausea and vomiting via input from the vestibulo-cochlear nerve (154). Opioids can alter the sensitivity of the

**FIGURE 69-3.** Location of the VC.

Interrelationships Between Neural Pathways That Mediate Nausea and Vomiting

Wood, G.J. et al. JAMA 2007;298:1196-1207.

**FIGURE 69-4.** Projections to VC capable of triggering emesis.

vestibular center, giving rise to movement-triggered nausea. When the VC is sufficiently stimulated, the dorsal motor nucleus of the vagus generates efferent impulses that trigger appropriate vasomotor and purely motor responses in a variety of tissues including respiratory, salivatory, gastrointestinal (GI), and diaphragmatic, and abdominal muscles to induce retching.

Identification of the specific neurotransmitters operating along these various pathways has permitted “rational” antiemetic therapy by antagonizing the implicated neurotransmitter receptors. Figure 69-4 lists the predominant neurotransmitters operating at each of the neural sites involved in nausea and emesis. Neurokinin 1 (substance P), serotonin (5HT<sub>3</sub>), dopamine, histamine, and acetylcholine are the best-characterized neurotransmitters. The GI tract, VC, and CTZ are rich in receptors for these neurotransmitters. Determination of the sites and neurotransmitters relevant for specific cases requires diligent clinical evaluation. This approach, formalized with a structured algorithm, allowed physicians to identify the cause of nausea and vomiting in 75% of a series of 61 hospice patients (155). For example, when nausea and vomiting are induced by chemotherapy, 5HT<sub>3</sub> is released in the gut, stimulates peripheral pathways, and acts via the CTZ to produce the symptoms; therefore, 5HT<sub>3</sub> antagonists such as ondansetron may provide significant relief (152). Conversely, motion-

associated nausea and vomiting depends on stimulation of muscarinic acetylcholine and histamine type 1 receptors and may be alleviated by antagonizing these receptors with scopolamine, dephendryamine, or promethazine (152).

Figure 69-4 illustrates redundancies in the distribution of neurotransmitters throughout the pathways that support nausea and vomiting. The limited number of receptor types is clinically advantageous as a single therapeutic agent can target multiple sites. 5HT<sub>3</sub> antagonists, for example, block both peripheral pathways and the CTZ.

### Causes

Chronic nausea and vomiting in advanced disease is most often multifactorial. Identification of all contributing factors increases the likelihood of successful management. Autonomic failure causing delayed gastric emptying has been frequently demonstrated among patients with advanced cancer. Autonomic failure is more common among cancer patients with poor performance status and malnutrition (156). The precise mechanisms underlying autonomic failure have yet to be fully elucidated. However, poor nutritional status suppresses the activity of the sympathetic nervous system in other clinical populations (157,158). The presence of cardiovascular effects, including postural hypotension, syncope, and fixed heart rate,

should direct attention to autonomic dysfunction as a driving etiology in chronic nausea.

Drugs frequently trigger or aggravate nausea in patients with advanced disease. Among cancer patients, opioid analgesia can cause nausea and vomiting after an initiation or an escalation in the dose. Opioids induce nausea by stimulating the CTZ, gastroparesis, constipation, and by increasing the sensitivity of the vestibular center (152). Many other drugs can cause nausea, including NSAIDs, antibiotics, iron supplements, tricyclic antidepressants (TCAs), selective 5HT<sub>3</sub> reuptake inhibitors, and phenothiazines.

Constipation and bowel obstruction are common among advanced cancer patients (155,159). There are many factors that predispose this population to the development of constipation, including immobility, poor oral intake, dehydration, autonomic failure, opioid analgesics, and other medications. Suspicion should be high for undiagnosed constipation in all patients with advanced disease. Bowel obstruction is less common, but nevertheless is an important potential contributor to chronic nausea (159). Most cancer patients experience a gradual progression from mild partial to complete obstruction, making the initial diagnosis challenging (160). Other potential contributors to chronic nausea include biochemical abnormalities (e.g., hypercalcemia, hyponatremia, liver failure), CNS metastases, increased intracranial pressure, and psychological factors (e.g., fear, anxiety). Deranged serum ion concentrations can also induce or aggravate nausea.

### Assessment

Characterizing the intensity, frequency, triggering factors, and qualitative dimensions of patients' experience is an essential initial step in the assessment of nausea and vomiting. Nausea should be distinguished from early satiety, bloating, and reflux symptoms. Determining patients' ability to keep fluids and solids down may indicate the need for nonoral routes of medication administration. In addition to a thorough history and physical examination including the frequency and quality

of patients' bowel movements, imaging and serological tests may be required to identify all factors contributing to nausea (148). An abdominal flat-plate x-ray can be helpful in determining whether constipation or obstruction is present. CT scans and MRIs of the brain or abdomen can elucidate the presence of an intracranial source or malignant obstruction. Contrast enhancement is needed for detection of leptomeningeal disease. Serological tests to exclude renal impairment, hepatic failure, and other metabolic abnormalities, including hypercalcemia, hypokalemia, and hyponatremia, should be initiated.

### Treatment

For the majority of patients, treatment of nausea will be pharmacological. Causative factors that can be feasibly eliminated or treated should be addressed. Efforts to treat potential contributing factors should not delay the delivery of appropriate pharmacological therapy. There are currently nine principal classes of drugs used as antiemetics in palliative care: butyrophenones, prokinetic agents, cannabinoids, phenothiazines, antihistamines, anticholinergics, steroids, 5HT<sub>3</sub> receptor antagonists, and benzodiazepines. As stated previously, the pathway(s) triggering nausea should be identified and pharmacological interventions chosen in a rational manner. Once the appropriate receptor has been identified, the most potent antagonist should be selected. Route of administration must be considered in patients for whom enteral administration is not feasible. Table 69-4 (152) lists commonly utilized agents in each of these classes.

Butyrophenones are dopamine antagonists including haloperidol and droperidol. As D<sub>2</sub> antagonists, they powerfully inhibit the CTZ particularly when used in combination with other drugs such as 5HT<sub>3</sub> receptor antagonists. Since these agents do not affect GI motility, they can be safely used in bowel obstruction (148). Additionally, haloperidol can be administered subcutaneously and is safe in renal failure.

**TABLE 69.4 Commonly Used Antiemetic Agents**

Class	Agent	Dose
Butyrophenones	Haldol	0.5–4 mg po, sc, or iv every 6 h
Prokinetic agents	Metoclopramide	5–20 mg po, sc, or iv before meals and hs
Cannabinoids	Dronabinol	1.25–10 mg every 12 h
Phenothiazines	Prochlorperazine	5–10 mg po or iv every 6 h or 25 mg pr
	Chlorpromazine	10–25 mg po every 4 h or 25–50 mg im or iv every 4 h, or 50–100 mg pr every 6 h
Antihistamines	Promethazine	12.5–25 mg po or iv every 6 h, or 25 mg pr every 6 h
	Diphenhydramine	25–50 mg po, sc, iv every 6 h
Anticholinergics	Scopolamine	1.5 mg transdermal patch every 3 d
	Hyoscyamine	0.125–0.25 sl or po every 4 h or 0.25–0.50 sc or iv every 4 h
Steroids	Dexamethasone	2–6 mg po, sc, or iv every 4–12 h wide range of recommended doses
5HT <sub>3</sub> receptor antagonists	Ondansetron	4–8 mg po or iv every 4–8 h
	Mirtazapine	15–45 mg po at hs
Benzodiazepines	Lorazepam	0.5–4 mg po or iv every 6 h

Prokinetic agents include metoclopramide and domperidone. Metoclopramide is the most commonly used drug in this category and antagonizes dopamine both centrally at the CTZ and peripherally in the GI tract. In addition, metoclopramide demonstrates weak antagonism at the 5HT<sub>3</sub> receptor. In addition to blocking CTZ receptors, metoclopramide helps to bring normal peristalsis in the upper GI tract. Metoclopramide has been advocated as an effective first-line agent for patients with chronic nausea (161).

Several studies have demonstrated the efficacy of the cannabinoid dronabinol as an antiemetic agent for the treatment of chemotherapy-induced nausea and vomiting (162–166). It is commonly dosed at 2.5 mg twice daily. Cognitive side effects including somnolence, confusion, and perceptual disturbance are frequent, particularly in patients with borderline cognitive impairment related to their disease or other medications. Dronabinol is generally considered a second- or third-line antiemetic.

Phenothiazines, such as chlorpromazine and thiethylperazine, have survived as a mainstay of antiemetic therapy. Phenothiazines exert their therapeutic effects by antagonizing dopamine. Their tranquilizing effects may or may not be desirable, contingent on each patient's symptom complex. One advantage is their availability in oral, rectal suppository, parenteral, and SR oral preparations. Their mechanism of action is distinct from the 5HT<sub>3</sub> antagonists and dexamethasone, so they can be effectively combined with these agents to augment therapeutic efficacy. Vigilance for extrapyramidal side effects should remain high throughout the duration of therapy. Twenty-five to fifty mg of diphenhydramine can be given to prevent these effects.

Antihistamines, including cyclizine, promethazine, and dimenhydrinate, are useful antiemetics that act to block histamine receptors in the VC and on vestibular afferents. They can be particularly useful if a vestibular afferent input is believed to contribute to the nausea. They are rarely used for antiemetic monotherapy in palliative care. Anticholinergics (e.g., scopolamine) are seldom used but have the advantage of sublingual, subcutaneous, and transdermal routes of administration. They are anticholinergic near the VC and additionally reduce peristalsis and inhibit exocrine secretions, thereby palliating nausea from GI obstruction (167,168).

Corticosteroids, particularly dexamethasone, are a common and highly effective component of aggressive antiemetic therapy. They have powerful nonspecific antiemetic effects that are currently not well understood. Corticosteroids can decrease edema surrounding tumors, thereby reducing intracranial pressure, which may contribute to nausea. They are extremely effective when used in combination with other agents, including metoclopramide and 5HT<sub>3</sub> receptor antagonists (169,170).

Serotonin antagonists have become increasingly accepted as first-line antiemetic agents. The 5HT<sub>3</sub> receptors have been discovered in the CTZ, VC, and in the terminals of the vagal afferents in the gut. Ondansetron, dolasetron, and granisetron, the principal commercially available 5HT<sub>3</sub> receptor antagonists, may be prohibitively priced for many patients. They have been widely used and researched for the prevention

and management of acute chemotherapy-induced nausea and vomiting (170,171). To date, no trials have been published evaluating the efficacy of 5HT<sub>3</sub> antagonists in the management of chronic nausea and less expensive D<sub>2</sub> antagonists are equally effective at the end of life (172,173). However, mirtazapine, an antidepressant that antagonizes the 5HT<sub>3</sub> receptor, has shown promise in alleviating nausea and other distressing, cancer-related symptoms (174,175). It is important to appreciate that 5HT<sub>3</sub> receptor antagonists may reduce the incidence of emesis without alleviating nausea.

The benzodiazepine lorazepam exerts its antiemetic effects within the CNS. It is highly effective when used in combination with other antiemetic agents. Additional desirable therapeutic effects include anxiolysis and amnesia. A trial conducted by Malik et al. suggested that lorazepam is highly effective in decreasing the incidence of anticipatory vomiting (176).

A variety of additional pharmacological agents are used to alleviate chronic nausea and vomiting. Thalidomide has enjoyed renewed interest in recent years for its anticachectic, antipyretic, sedative, and antiemetic properties (177). Thalidomide is believed to exert its antiemetic effects via a central mechanism. The progestational agent megestrol acetate has been predominantly studied for its anticachectic properties. However, several studies reported significant reductions in nausea following the initiation of megestrol therapy (178,179). Octreotide, a somatostatin analogue, effectively reduces nausea in patients with intestinal obstruction by reducing GI secretions (180,181). The neurokinin-1 antagonist aprepitant alleviates chemotherapy-induced nausea and vomiting and may control nausea of alternate causes (182,183). Olanzapine, an atypical antipsychotic, has shown promise in the treatment of nausea (184–186) presumably via blockade of a variety of receptors including dopamine, acetylcholine, histamine, and serotonin receptors (152).

Despite growing insight into the neurotransmitters responsible for nausea and vomiting and enthusiasm for a rational, mechanistic approach to palliation, several authors advocate empirical initial treatment with D<sub>2</sub> receptor antagonists such as metoclopramide, prochlorperazine, or haloperidol irrespective of the implicated pathways (161,187–189). There have been no head-to-head comparisons of mechanistic and empirical approaches. However, proponents of mechanistic approaches acknowledge that first-line use of D<sub>2</sub> receptor antagonists makes sense as these agents block CTZ activity (152). It has also been suggested that multiagent regimens such as the combination of a corticosteroid with either a 5HT<sub>3</sub> receptor antagonist (167,190) or metoclopramide (191) offer the best chance of effectively managing chronic nausea. However, a recent trial showed no benefit over placebo when dexamethasone was added to metoclopramide for patients with nausea related to advanced cancer (169).

When a first-line agent fails to adequately alleviate nausea and vomiting, the adequacy of dosing should be ascertained. Often, as-needed dosing proves insufficient and patients require around-the-clock dosing (144). Adding a second agent is often preferred to changing antiemetic agents since multiple neurotransmitters act on the relevant sites (152).

Multiple nonpharmacologic approaches to controlling nausea and vomiting have been proposed and their efficacy has been demonstrated in clinical trials (192,193). Simple measures such as eliminating strong odors and other emetic triggers, consuming small frequent meals, and reducing oral intake during intensely emetic intervals are beneficial (194,195). Self-hypnosis, progressive muscle relaxation, biofeedback, guided imagery, cognitive distraction, music therapy, and systemic desensitization are behavioral techniques that have been used with varying degrees of success. The combined use of guided imagery and progressive muscle relaxation or music is highly effective in reducing chemotherapy-induced nausea and vomiting. Such integrated regimens may be most effective at reducing nausea, although further trials are required before a definitive statement can be made.

Acupuncture and acupressure have been widely used in the treatment of chemotherapy-induced nausea, motion sickness, and hyperemesis gravidarum. Several rigorously designed clinical trials have found that acupuncture can mitigate nausea associated with chemotherapy administration (196,197). Studies have focused on stimulation of pericardium or master of the heart 6 point located on the volar surface of the forearm approximately three finger breadths proximal to the wrist crease. Few studies have investigated acupuncture for chronic nausea in the terminally ill. An isolated study evaluated the use of acupressure wrist bands in advanced cancer patients and found them to be ineffective (198).

## ANOREXIA AND CACHEXIA

Anorexia describes the lack or loss of appetite leading to reduced oral intake and weight loss. Cachexia, in contrast, is a maladaptive state of metabolic dysfunction characterized by (a) progressive wasting of fat and muscle tissue, and (b) disruption of preferential fat loss induced by starvation (199). Wasting occurs out of proportion to reduced oral intake, is resistant to conventional nutritional support, and preferentially affects skeletal muscle over cardiac or smooth muscle (200). Vital organs remain relatively preserved even in advanced cachexia.

Anorexia and cachexia are important clinical problems in advanced disease because they associate with reduced performance status, as well as increased risk of treatment failure, side effects, and mortality (201,202). Cachexia is the most common single cause of death documented in cancer patients being directly responsible for 25% deaths and affecting about half of all patients (203). Functional debility associated with cachexia may be profound due to impaired respiratory muscle function when total weight loss exceeds 15% (204). Death generally occurs when patients lose 25% to 35% of their total body weight (205,206).

### Epidemiology

The prevalence of cachexia depends on the stage of the inciting disease process. For example, although over 50% of all patients with cancer lose body weight, weight loss occurs much

more commonly among patients with stage IV cancer with the prevalence rising as high as 86% in the last 1 to 2 weeks of life (207). As many as 20% of all cancer deaths are caused directly by cachexia (208). Cachexia is a common characteristic of the end stages of many chronic illnesses with estimated prevalences as follows: congestive heart failure (CHF), 16% to 36% (209,210), COPD, 27% to 33% (211,212), and ESRD, 30% to 60% (213).

### Pathophysiology

Disequilibrium between oral intake and muscle wasting results from interactions between the host and the tumor or disease processes, in the case of noncancer cachexia, which remain partially understood. Tumors elaborate local proinflammatory cytokines (214,215) that activate host inflammatory cells, which pass through the tumor, circulate systemically, and ultimately induce the hepatic acute phase protein response (APPR) (214–216). Interleukin-6 has been implicated in APPR induction though a host of other cytokines may participate as well (216–218). Tumors also secrete 2 well-characterized pro-cachectic factors: proteolysis-inducing factor (PIF) (219,220) and lipid-mobilizing factor (LMF) (221–223). The complex systemic interactions that may underlie cachexia are illustrated in Figure 69-5.

Host factors contribute to cachexia through the tumor-induced APPR and the neuroendocrine stress response. The APPR is a part of the body's systemic reaction to tissue injury, neoplastic growth, and infection (203). Up to 50% of patients with solid tumors may present with APPR, manifest in elevated serum C-reactive protein levels, at the time of diagnosis (224). Although elevated acute phase reactants are strongly associated with cachexia, causal mediators between these phenomena have not been definitively identified. One hypothesis suggests that the liver becomes a protein sink competing with skeletal muscle for dwindling amino acid supplies (225). Mechanisms through which the neuroendocrine stress response may contribute to cachexia are also unclear. Increased circulating levels of the anabolic skeletal muscle mediators insulin, growth hormone, and testosterone coupled with decreased circulating levels of the catabolic mediators cortisol and myostatin implicate the neuroendocrine stress response. Further, autonomic dysregulation, another manifestation of the stress response, is more prevalent in cachectic patients (226,227). That such associations may reflect epiphenomena rather than direct causal linkages has been a disappointing realization for cachexia researchers as is evident in their study of TNF- $\alpha$ .

Brief mention of TNF- $\alpha$  is warranted as it has been a focus of intense cachexia research for decades and has been the focus of recent treatment trials. The discovery that TNF- $\alpha$  induces cachexia in animal models, with the typical increased protein degradation that plagues affected patients, led investigators to hope that TNF- $\alpha$  predominantly mediates human cachexia and could be a therapeutic target (228). However, clinical trials with TNF- $\alpha$  synthesis and receptor blockade have been disappointing and therapeutic interest has shifted to PIF (222,223,229).

**FIGURE 69-5.** Systemic interactions mediating cachexia.

At the cellular level, the importance of reduced protein synthesis relative to increased protein degradation in cachexia is a source of debate with results differing across studies (199). Several models of cachexia suggest that both are important and must be targeted for therapeutic efficacy. Events underlying reduced protein synthesis are complex but relate to dysregulated phosphorylation of factors that initiate protein translation (230). Efforts to understand accelerated protein degradation have focused on the ubiquitin-proteasome pathway that appears to be of major importance in conditions associated with significant loss of muscle mass (231). The pathway has been comprehensively reviewed (232). In brief, multiple ubiquitin molecules are serially conjugated to proteins destined for degradation that distinguishes them from the 26S proteasome complex that confines proteases preventing indiscriminate degradation. Several enzymes that ligate ubiquitin to myosin heavy chain proteins and to troponin 1 are highly expressed in muscle wasting conditions and are believed to play an important role in cachexia (233–235). The literature is mixed regarding the precise impact of various cytokines and procachectic factors on the ubiquitin-proteasome pathway.  $\text{TNF-}\alpha$ , IL-6, and PIF influence transcription of ubiquitin pathway proteins in animal models; however, whether results apply to clinical cachexia is unclear (199).

Of significance for physiatrists is the growing recognition that physical activity may play an important mediating role in the induction and progression of cachexia. Historically, the suspicion that increased host resting energy expenditure (REE) contributed to cachexia raised concern over exercise. However, the recognition that host REE varies as reflected in reports of reduced (236), normal (237), or elevated (238)

energy expenditure, coupled with reports that cancers with the highest prevalence of cachexia (gastric and colorectal) are associated with reduced REE has put fears to rest. A study of cachectic pancreatic cancer patients revealed their REE and total energy expenditure was comparable to home-based spinal cord injured patients (239), levels that may aggravate sarcopenia (240). Clinical efforts to treat cachexia through physical activity are described in the treatment section as follows.

## Treatment

Cachexia treatment options have become increasingly limited as evidence demonstrates poor efficacy in previously standard therapies. Nutritional approaches are now deemphasized since dietary counseling and total parenteral nutrition fail to attenuate cachexia (241). As discussed more fully in the nutritional section, unless patients are malnourished, strategies to enhance dietary intake do not improve QOL, functional performance, or survival.

**Appetite stimulants:** Pharmacologic interventions have survived empirical scrutiny little better than dietary approaches. Appetite stimulants, formerly the standard of care and still widely used, target anorexia and may induce weight gain but do not increase lean muscle mass or extend survival in cancer cachexia. Progestational agents are synthetic derivatives of progesterone for oral use with anabolic effects that are independent of their antitumor properties. The progestational agent megestrol acetate, believed to downregulate cytokine synthesis and the subject of recent reviews and meta-analyses, has proven disappointingly limited in its capacity to decelerate cachexia (242,243). Megestrol acetate improves appetite in roughly 30% of treated patients leading to short-term weight

stabilization but similar to other nutritionally based approaches does not enhance QOL or survival (244–246). Loss of lean muscle mass remains unaffected by megestrol acetate (247). In light of their potential toxicities, venous thrombosis, peripheral edema, vaginal bleeding, impotence and adrenal insufficiency, the cost-to-benefit ratio of progestational agents may not be defensible for most patients (241,248,249). The usual dosage of megestrol acetate is 80 to 160 mg orally four times daily.

Corticosteroids have also been widely utilized to stimulate appetite and thereby attenuate cachexia. Glucocorticoids suppress TNF- $\alpha$  production and inhibit prostaglandin synthesis. Multiple studies evaluating the effect of dexamethasone and prednisolone have failed to demonstrate significant weight gain (132,250–252). Although corticosteroids may improve patients' subjective well-being, they have a concerning side-effect profile and hence are not suitable for long-term use (241). A steroid trial in cachectic patients may be warranted for enhanced sense of well-being and to treat associated adverse symptoms. However, there is no current evidence to suggest the reversal or mitigation of cachexia can be expected.

Cannabinoids are marijuana derivatives that act either by interfering with cytokine activity or by acting on endocannabinoid receptors in the hypothalamus, intestine, and adipose tissue and have putative orexigenic effects (245,253). However, a well-conducted trial of delta-9-tetrahydrocannabinol versus cannabis extract versus placebo failed to demonstrate significant differences between the treatment arms with respect to appetite or QOL (254). In light of a side-effect profile that may limit use of analgesics and other symptom-modifying agents (e.g., vomiting, drowsiness, mental clouding) cannabinoids cannot be currently endorsed for management of cachexia.

*The upstream approach:* Increasing implications of proinflammatory cytokines in animal cachexia models has spurred researchers to evaluate therapies targeting events “upstream” of intracellular proteolytic pathways. Drugs of interest are those capable of inhibiting the elaboration of cytokines (pentoxifylline, melatonin, cyclo-oxygenase-2 inhibitors, and thalidomide) and those that interfere with cytokine actions (anticytokine antibodies, suramin, and anti-inflammatory cytokines) (241,255). Similar to the promising results in murine models, most clinical trials in humans have also been encouraging. Randomized, controlled designs have been used to evaluate the following agents: pentoxifylline (256), melatonin (257,258), ibuprofen (259), etanercept (260) (TNF- $\alpha$  inhibitor), and thalidomide (261–263) with results being mixed. Only thalidomide reversed loss of lean body mass in both open-label and controlled trials (261–263). Further, thalidomide treatment was associated with improvement in a broad array of adverse symptoms (261–263). In mixed patient populations, 300 mg daily produced an average weight gain of 4.5% compared with 0.9% in patients receiving placebo (264). Of note, given thalidomide's complex immunomodulatory and anti-inflammatory properties with promiscuous effects on sundry physiological systems, it remains unclear whether these positive trials, in fact, support the upstream approach (261–263).

*The “downstream” approach:* Growing insight into the biochemical and molecular mechanisms responsible for muscle degradation has targeted specific intracellular pathways for potential therapeutic intervention. Strategically, such intracellular approaches are, as yet, theoretically based and clinically limited to eicosapentaenoic acid (EPA) trials. EPA interferes with proteasome activity through different mechanisms in experimental conditions and may, therefore, inhibit the ubiquitin-proteasome pathway (265). The results of promising pilot studies administering EPA to patients with cancer-related cachexia were not been replicated in large, multicenter trials (266,267). However, in a *post hoc* analysis of this trial, a significant improvement in physical functioning was detected among patients receiving EPA (268). Adding EPA to megestrol acetate added no incremental benefit with respect to patients' performance status or QOL (244). A recent Cochrane review concluded that empirical data do not currently support use of EPA for cancer cachexia (269).

*Stimulation of muscle protein anabolism:* The capacity of exercise to increase muscle mass and endurance has led investigators to study its efficacy in cachexia. Animal models suggest that exercise may be a useful adjunctive therapy. In murine models, spontaneous, semivoluntary, and forced-endurance exercise increased protein synthesis in skeletal muscle (270–273). Translation of these promising results to human trials has been exceedingly limited. A program of combined resistive and aerobic training in male AIDS patients significantly enhanced strength, but did not alter lean body mass (274). Concurrent testosterone use during a progressive resistive exercise program afforded more promising results by significantly increasing extremity cross-sectional areas in patients with AIDS-related wasting (275).

Anabolic androgenic steroids administered without prescribed physical activity have proven beneficial in a variety of disease states: severe burns (276), HIV infection (277), COPD (278), and cancer (279). However, findings remain insufficiently robust to support routine use of these agents. Nandrolone decanoate and oxandrolone have been most widely studied with neither agent emerging as superior for the management of cachexia (265).

At present, few definitive conclusions can be drawn regarding the treatment of cachexia. Nutritional supplementation alone is of little benefit. Pharmacologic interventions, excepting thalidomide, have been generally disappointing. A trial of conservative exercise with or without pharmacological manipulation is indicated in most patients.

## DYSPNEA

Dyspnea has been defined as an uncomfortable awareness of breathing. Although most people can intuit the experience of this symptom, there is no universally sanctioned definition. For many patients, the description of, “an unpleasant sensation of difficult, labored breathing,” adequately characterizes their experience. Dyspnea may undermine functional performance

and serve as a deterrent to physical activity making it an important therapeutic target for physiatrists.

### Epidemiology

Prevalence rates of dyspnea at the end of life range widely depending on the population studied and the mode of assessment. In the National Hospice Study, 70% of 1,754 patients experienced dyspnea during the last 6 weeks of life (280). More than 28% of these patients rated the severity of their symptom as moderate or worse. Prevalence rates of between 24% and 60% have been reported in cancer cohorts, with unexpectedly high rates among patients with extrathoracic malignancies (281–283). Dyspnea is also commonly experienced by patients with noncancerous illnesses. The prevalence of dyspnea varies across diseases: COPD, 95%; CHF, 61%; stroke, 37%; amyotrophic lateral sclerosis, 47%; and dementia, 70% (284,285). Reported prevalences among patients with AIDS range from 11% to 62%, although changes since the advent of modern HIV therapies have not been well characterized (286–288).

Despite epidemiological inconsistencies, dyspnea is clearly a common symptom in patients with advanced disease and prevalence rates increase near the end of life. Reports suggest that dyspnea is more problematic in men, older patients, and those with lower self-reported QOL (289,290).

### Pathophysiology

The mechanisms that regulate normal breathing participate in the experience of dyspnea through complex interactions between breathing abnormalities and the perception of those abnormalities in the CNS. Regulation of breathing depends on interplay between the CNS respiratory center, chemoreceptors, and afferent input from respiratory muscles. Figure 69-6 illustrates a proposed schema for the interplay between these elements. The medulla houses the respiratory center, which receives input from central and peripheral chemoreceptors, as well as peripheral

mechanoreceptors. The respiratory center also receives input from the cerebral cortex (291,292). Chemoreceptors, both centrally and in the periphery, respond to levels of oxygen and carbon dioxide in the blood. These chemoreceptors stimulate the respiratory center and possibly the cerebral cortex, leading to an increase in respiratory rate (293,294). The sensation of dyspnea may be intensified through peripheral mechanoreceptor-induced stimulation of the cerebral cortex in response to tachypnea driven by the respiratory center. Mechanoreceptors sense altered muscle tension within the abdominal wall, diaphragm, and accessory muscles of respiration in tension within the lung.

Dyspnea depends on cortical stimulation. Stimulation of mechanoreceptor can produce the sensation of dyspnea in the absence of increased respiratory activity (292,294). Three principal abnormalities give rise to dyspnea. These include an increase in respiratory effort to overcome a certain load (e.g., pleural effusion), an increase in the proportion of respiratory muscle required to maintain normal workload, and an increase in ventilatory requirements (e.g., hypoxemia) (292). Often all three abnormalities coexist. A striking inconsistency between symptom intensity and the level of functional abnormality often characterized dyspnea. For example, severe asthmatics may not report subjective dyspnea despite marked airflow obstruction (295). Similar findings have been noted in COPD patients with severe respiratory abnormalities (296). Psychological factors can strongly influence the intensity with which dyspnea is experienced and expressed (289,297).

### Causes

Abnormalities that directly and indirectly affect the cardiopulmonary system can give rise to dyspnea. Premorbid cardiac or pulmonary disease can leave patients exceedingly vulnerable to dyspnea with minimal physiological derangement.

Cancerous sources of dyspnea abound. Tumor within the lung parenchyma, pleura, or pulmonary lymphatics can significantly reduce oxidative capacity. Cancerous spread may arise from primary intrathoracic tumors or from metastatic disease. Tumorous caking of the pleura as seen in mesothelioma can cause restrictive lung disease with resultant dyspnea. Malignant pleural and pericardial effusions may produce a subjective sense of air hunger. Tumor can also extrinsically compress portions of the airway.

Abdominal ascites and hepatic distension can limit diaphragmatic excursion. Severe anemia may produce dyspnea. Cachexia with associated muscle wasting will increase the percentage of maximal muscle capacity required for normal breathing rendering affected patients vulnerable to rapid respiratory muscle fatigue. Infectious etiologies (e.g., pneumonia) must be considered, particularly in neutropenic patients. Despite the variety of potential causes, dyspnea often persists after reversible causes have been addressed.

### Assessment

Dyspnea varies in intensity according to patients' activity levels. Patients may attempt to limit their experience of

**FIGURE 69-6.** Factors regulating normal breathing. (Adapted from Bruera E, Sweeney C, Ripamonti C. Management of dyspnea. In: Berger A, Portenoy RK, Weissman D, eds. *Principles and Practice of Palliative Care and Supportive Oncology*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2002:358.)

dyspnea by curtailing physical activity (298). Consequently, symptom intensity ratings alone may not adequately capture symptom severity. Comprehensive assessment should characterize dyspnea-related activity avoidance (299). Assessment should focus on potential contributing clinical factors, particularly those that may be reversible. This mandates a comprehensive history and physical examination. Attention should be paid to associated signs and symptoms such as chest pain, fever, rigors, cough, cachexia, abdominal distension, and pleurisy. Associated symptoms, particularly pain and anxiety that correlate with dyspnea intensity, may prove to be critical therapeutic targets (289,290). Helpful diagnostic tests include chest radiography, electrocardiography, echocardiography, pulmonary function tests, arterial blood gases, serum electrolytes, and complete blood count. Abdominal and chest computed tomography scans can elucidate the extent of tumor spread within these body cavities.

## Treatment

Symptomatic treatment of dyspnea should occur in parallel with efforts to manage specific pathophysiological contributors. For patients with cancer, the initiation of a novel chemotherapy regimen may offer greatest relief if dyspnea is related to tumor effects. Irradiation, including brachytherapy, also offers the capacity to rapidly reduce local tumor burden and associated obstruction (300). Drainage of pleural or pericardial effusions or abdominal ascites may afford dramatic and abrupt relief. Empiric antibiotic therapy may be appropriate if pneumonia is suspected. Pulmonary consultation may clarify the utility of bronchoscopic approaches to address luminal obstruction or narrowing (298). Rigid bronchoscopes, balloon dilatation, lasers, electrocautery, stents, argon plasma coagulation, and cryoprobes have been utilized to address airway obstruction, generally for intraluminal lesions (298,301).

Symptomatic management is based on three principal elements: oxygen, pharmaceuticals, and supportive measures (302). Randomized, controlled studies have reported dyspnea relief in hypoxic patients with cancer receiving supplemental oxygen (303–307). Patients without rest or exertional hypoxia did not derive benefit. Helium-enriched air may be superior to either room or oxygen-enriched air for patients with cancer or COPD experiencing exertional dyspnea (308,309). A majority of well-designed trials in patients with COPD have shown supplemental oxygen to be beneficial (310–312). However, Liss and Grant found that the delivery of different oxygen concentrations was not superior to room air on resting dyspnea in COPD patients (313). A recent systematic review found little evidence that oxygen enhances functional capacity in COPD patients (314). Use of noninvasive positive-pressure ventilation during walking may enhance the benefits of oxygen among patients with severe COPD (315). Results are mixed in controlled, randomized trials evaluating the effect of supplemental oxygen in patients with CHF (316,317). A trial of supplemental oxygen is warranted in all dyspneic patients given the ease with which it can be conducted and its benign side-effect profile.

Pharmacotherapy of dyspnea is based on a limited number of drug classes: opioids, benzodiazepines, corticosteroids, and bronchodilators. Opioids have been extensively used to palliate dyspnea. A majority of studies evaluating the efficacy of opioids in the treatment of COPD-associated dyspnea have reported benefit (318–326). Efficacy was demonstrated using hydrocodone, dihydrocodeine, hydromorphone, codeine, and morphine. All trials of opioid pharmacotherapy for cancer-related dyspnea using subcutaneous morphine reported success (273,327–332). Nebulized morphine is not effective (333–335). Morphine should be administered with caution in patients with no prior history of opioid exposure. Increased levels of  $\text{PCO}_2$  were found following continuous morphine infusion in opioid naïve patients (331). Studies of morphine use in patients with prior histories of opioid exposure did not result in increased  $\text{PCO}_2$  (38,327–331). At present, there are no definitive guidelines for dosing opioids to treat dyspnea. One report found 25% of patients' usual 4-hourly dose was sufficient to significantly reduce the intensity of dyspnea (327).

Benzodiazepines are routinely used for the symptomatic relief of dyspnea despite convincing evidence of their efficacy. Four of five controlled studies evaluating the effect of benzodiazepines for the treatment of COPD- and exercise-induced dyspnea failed to show any benefit (336–340). The use of benzodiazepines is warranted in the management of dyspnea associated with anxiety or a panic disorder. Otherwise, current literature does not support their use. However, the combination of morphine and midazolam alleviated dyspnea to a significantly greater degree than either morphine or midazolam alone (341).

Corticosteroids are commonly used to treat dyspnea associated with cancerous infiltration of pulmonary lymphatics and superior vena cava syndrome. Further, they have a long history of reducing bronchospasm associated with asthma and COPD (342,343). A trial of systemic or inhaled corticosteroids may be warranted if excessive mucus production or inflammatory changes in the airway contribute to dyspnea (298). The cost-to-benefit ratio of corticosteroid therapy should be carefully evaluated given their potential adverse impact on diaphragmatic function, particularly in cachectic patients.

Bronchodilators, both orally administered and nebulized, have proven to be extremely useful in the management of bronchospasm associated with asthma and COPD (342). Many cancer patients with dyspnea have a history of smoking or COPD, and dyspnea may be associated with airflow obstruction in patients with lung cancer (344). A trial of bronchodilator therapy is warranted when airflow obstruction may be playing a role in dyspnea. Aminophylline, theophylline, and caffeine improve diaphragmatic contractility in healthy individuals (345). Cachectic patients with generalized muscle weakness may benefit from xanthines.

Nebulized furosemide has been proposed as a treatment for dyspnea in patients with advanced cancer (346,347). However, an isolated trial detected mild worsening of dyspnea in patients receiving furosemide (347). In the absence of

further evidence, nebulized furosemide cannot be endorsed as a treatment option.

General supportive measures can significantly enhance functional status and relieve distress in dyspneic patients. Patients able to tolerate aerobic conditioning may experience enhanced functional capacity, although the benefits of exercise remain largely theoretical in the palliative setting. Clearly, exercise interventions must be conducted in a manner sensitive to clinical context, prognosis, and patient preference. Pacing strategies and provision with assistive devices can reduce the work involved in activities of daily living, thereby affording dyspneic patients increasing autonomy and comfort. The benefits of continuous and intermittent positive pressure ventilation for patients with COPD, CHF, and neuromuscular respiratory dysfunction are discussed elsewhere in this text.

Patient and family education can have a powerful impact in reducing anxiety. Patients often fear dying of asphyxiation. Provision with a plan for emergency intervention may assuage, if not eliminate, this fear. Nursing-led interventions emphasizing coping with the psychological aspects of breathlessness reduce dyspnea (348–350). The benign nature of such interventions and their consistent efficacy argues that they should be integral to the palliation of dyspnea.

## HICCUPS AND COUGH

Uncontrolled hiccups and cough can demoralize patients, and interfere with sleep, hydration, and nutrition. If persistent, these symptoms can render patients exhausted, malnourished, and vulnerable to medical morbidities. Hiccups, or singultus, are defined as repeated, involuntary contractions of one or both sides of the diaphragm (generally unilateral) and the intercostal muscles, terminated by abrupt closure of the glottis (351). This produces the characteristic sound of “hic.” In contrast to hiccups, which have no known purpose, cough is a natural defense of the body to prevent entry of foreign material into the respiratory tract.

### Epidemiology

The prevalence of hiccups in different patient populations in the advanced stages of disease has not yet been characterized. Cough has been anecdotally described as a distressing symptom in patients with CHF, uncontrolled asthma, AIDS, and various cancers. A systematic review of symptom prevalence in patients with incurable illnesses revealed a cumulative cough prevalence of 28% among 12,000 patients in 24 studies (207). In a series of 289 patients with non-small cell lung cancer, cough afflicted more than 60% of the patients at presentation and prevalence increased to 80% before death (283).

### Pathophysiology

The physiology of hiccups is poorly understood. A proposed hiccup reflex arc consists of afferent impulses transmitted via the phrenic or vagus nerves or the sympathetic ganglia, with efferent signals transmitted via the phrenic nerve to the

glottis, diaphragm, and accessory muscles of respiration (351). Connections between the limbs occur at the levels of the spinal cord, a possible hiccup center in the cervical cord between C3 and C5, and higher CNS centers (352,353). Irritation, inflammation, or distension of viscera, primarily esophagus, liver, and stomach may trigger hiccups. Toxic and metabolic factors may also initiate and sustain hiccups including uremia, hyponatremia, hypokalemia, hypocalcemia, ethanol, and some chemotherapeutic agents (351).

Cough is similarly generated through a reflex arc that produces respiratory flow rates high enough to dislodge mucus and foreign substances from the lining of the airways. The cough reflex consists of afferent fibers housed within the vagus, trigeminal, and phrenic nerves. These fibers carry impulses generated by “cough” receptors at the termini of A $\delta$ - and C-fibers found within the larynx, respiratory epithelium, tympanic membranes, esophagus, pericardium, and sinus mucosa. As with nociceptive afferents, A $\delta$ -fibers convey impulses produced by mechanical stimuli, while C-fibers convey impulses produced by chemical stimuli (354,355). Inflammatory neuromodulators, such as prostaglandins, may influence receptor thresholds for depolarization (356). The impulses travel to cough centers within the medulla. Efferent impulses travel via the vagus, phrenic, and spinal nerves to the glottis and respiratory muscles (356,357). The resultant cough occurs in three phases: first an initial inspiratory phase, second a compressive phase, and last an expulsive phase (358).

### Causes

In theory, many pathophysiological processes may engender hiccups with the most common being an overdistended stomach (359). Other common causes in the palliative setting include esophagogastric irritation, ileus, and peridiaphragmatic metastases. Causes of hiccups associated with advanced disease are listed in Table 69-5.

Cough often results secondary to local effects of the disease process. Tumors can irritate adjacent thoracic, abdominal, and neurologic structures to produce cough as occurs with endobronchial tumor, pericardial disease/effusion, or vocal cord paralysis. Infection may physically strip away epithelium, exposing sensory nerves and increasing the sensitivity of these structures to mechanical and chemical stimuli (360). Patients with both cancer and noncancer illnesses frequently cough consequent to aspiration indicating a need for clinical evaluation (361). Upper airway cough syndrome due to rhinosinus conditions, asthma, and gastroesophageal reflux disease is the most common source of cough in the general population and may also afflict patients in the palliative setting (362,363).

### Assessment

History from the hiccapping patient should include data on recent bowel movements, oral intake, medication changes, and any associated abdominal or epigastric symptoms. Physical examination should focus on evidence of gastric distention. Neurologic examination may identify potential malignant sources of neural irritation triggers for both hiccups and

**TABLE 69.5 Neurocognitive Rationale for and Against Supplemental Hydration in the Palliative Setting**

CON	PRO
Comatose patients do not experience symptom distress	Dehydration can lead to pre-renal azotemia, which in turn can lead to accumulation of drug metabolites leading to delirium, myoclonus, and seizures
Parenteral fluids may prolong dying	There is no evidence that fluids prolong the dying process
With less urine, there is less need to void and use catheters	Providing hydration can maintain the appearance of “doing something,” even though there may be no medical value, and thus ease family anxiety around the time of death
With less GI fluid, there can be less nausea and vomiting	
With less respiratory tract secretions, there can be less cough and pulmonary edema	
Dehydration can help reduce distressing edema or ascites	
Dehydration may be a “natural” anesthetic to ease the dying process	
Parenteral hydration can be uncomfortable (e.g., needles/catheters) and limit patient mobility	

cough since symptoms are mediated by reflex arcs. Serologic evaluation for metabolic derangements must be considered when routine evaluations are unrevealing. Imaging can localize tumor compression involving the neural reflex arcs or intrathoracic and peridiaphragmatic structures.

Potentially useful evaluations specific to the patient with cough include chest or sinus x-rays, and spirometry with pre- and postbronchodilator and histamine challenge. Upper GI endoscopy and 24-hour esophageal pH monitoring may also be useful. Such tests can be highly distressing and possibly dangerous for patients with advanced disease. Therefore, their utility must be weighed against how the information will alter management. An empiric medication trial may be the more clinically appropriate and humane approach.

Symptom-specific questionnaires allow subjective assessment of patients' experience and associated distress. Both the *Leicester Cough Questionnaire* (364) and the *Cough Specific Quality of Life Questionnaire* (365) yield valid and reproducible results.

### Treatment

Proposed treatments of hiccups are extensive. Nonpharmacological strategies include simple respiratory maneuvers (e.g., breath holding, rebreathing into a bag, compression of the diaphragm), nasal and pharyngeal stimulation (e.g., pressure on the nose, inhalation of a stimulant, traction of the tongue), vagal stimulation (e.g., ocular compression, carotid massage), psychiatric treatment (e.g., behavioral therapy), gastric distension relief (e.g., fasting, use of an NG tube, lavage), and phrenic nerve disruption via anesthetic injection

(353,359,366,367). The efficacy of these approaches has not been rigorously assessed in clinical trials.

More empirical data support pharmacological hiccup treatments but should always be combined with definitive, disease-oriented therapies if feasible. If tumor effects are suspected, cytoreductive therapies, for example, radiation, may achieve symptomatic relief. The medication classes commonly used to treat hiccups include phenothiazines (chlorpromazine, prochlorperazine), butyrophenones (haloperidol), prokinetic agents, and anticonvulsants. Medication choices should reflect patients' prognoses and functional levels. Chlorpromazine is the only FDA-approved agent for hiccups with dosing as follows: 25 to 50 mg orally tid or qid, or parenteral infusion of 25 to 50 mg in 500 to 1,000 mL normal saline over several hours. Haloperidol, 2 to 5 mg orally or subcutaneously to load followed by 1 to 4 mg orally tid, may have other desirable symptom control properties (351,368,369). The anticonvulsants gabapentin (300 to 400 mg orally tid), phenytoin (200 mg IV push to load followed by 300 mg orally qd), and valproic acid (5 mg/kg orally, then increase by 250 mg/wk until hiccups resolve or subcutaneously every 12 hours) may be preferred for neurogenically mediated hiccups. In contrast, hiccups attributed to gastric distension may preferentially respond to metoclopramide (10 mg orally qid) (368,369). Baclofen administered 5 mg orally tid failed to eliminate hiccups but provided symptomatic relief in a blinded, randomized trial (370). Nifedipine (10 to 80 mg orally bid) represents a third-line agent that may be preferred in cases of dose-limiting CNS sedation. Agents from different classes may be cautiously combined given the potential for

sedation, cognitive deterioration, and seizures with multiple centrally acting drugs.

Cause-directed cough treatment may increase the likelihood of successful management and avoid adverse consequences (362). Disease-modifying therapies such as tumor-directed radiation or chemotherapy may alleviate cough but are frequently limited in the palliative setting (371,372). Managing potentially contributory etiologies such as GERD or asthma represents an important initial step. Nonpharmacological interventions involve avoiding stimuli that trigger coughing fits such as smoking, cold air, exercise, or overeating. When excessive or viscous mucus production contribute to cough hydration, chest physiotherapy and humidification of air may be helpful.

Pharmacological management of cough generally involves one or more of the following medication classes: opioids, protussive agents, nonopioid antitussive agents, bronchodilators, and steroids. Opioids effectively suppress cough peripherally by binding to receptors in the lung and centrally by suppressing the cough center (373,374). Codeine has been most widely used, but its superiority over other commercially available opioids has been questioned (373,375). Hydrocodone dosed from 5 to 30 mg/d reduced cough frequency by a median of 70% (376). Slow-release morphine sulfate effectively suppressed cough in a controlled, blinded trial (377).

Nonopioid therapies may be effective in cause-directed treatments. Protussive agents including inhaled ipratropium bromide, nebulized saline, guaifenesin, and carbocysteine influence mucus secretion and viscosity to promote its elimination (373,378). These therapies are ineffective in patients with profound weakness (379). Few of the commercially available antitussives offer significantly greater efficacy than opioid therapy (362). Dextromethorphan has the most extensively documented track record in palliative care (380). Benzonotatate is also widely used. Its efficacy in the palliative setting is suggested by limited case series (381,382). Local anesthetic preparations (e.g., lidocaine or bupivacaine) delivered by nebulizer have suppressed chronic cough (380).

Some patients obtain relief with the use of  $\beta_2$ -adrenergic agonists such as albuterol, two or three inhalations every 4 to 6 hours, or 0.5 mL albuterol solution in 2 mL saline via nebulizer every 4 to 6 hours. The use of steroids may afford relief to some patients. Inhaled steroids such as flunisolide, two puffs twice daily, and triamcinolone, two to four puffs four times a day, may be tried as initial therapy (383). For patients who remain unresponsive to inhaler preparations, a trial of systemic steroids may prove beneficial.

## HYDRATION AND NUTRITION

For many patients and their families, the provision of sustenance symbolizes preservation of life. Therefore, hydration and nutritional support may assume significance that extends beyond clinical concerns. To be effective in mediating the discussion of whether supplemental feeding and hydration are

appropriate, a clinician must appreciate the subtleties that may influence communication. The ethics of providing artificial nutrition and hydration (ANH) have been fiercely debated in the palliative care literature. A thorough discussion of the pertinent issues is beyond the scope of this chapter. The interested reader is referred to several excellent position papers (384–387). Although the majority of consensus statements hold that ANH is an interventional therapy that can be refused like any other, some contenders maintain that ANH constitutes basic care and must be provided. The authors acknowledge that prognoses, comorbidities, and etiologies differ widely and may dictate futility of ANH. Hence, broad generalizations are of little use.

Empirical evidence supports the use of ANH to extend survival among patients: in a permanent vegetative state (388), with extreme short-bowel syndrome (389), with amyotrophic lateral sclerosis-related dysphagia (390), in the acute phase of stroke or head injury (391,392), receiving short-term critical care (393), and with proximal obstruction of the bowel (394).

## Epidemiology

The majority of patients who die in the United States and Canada do so while receiving either supplemental nutrition or hydration (395). Data on the prevalence of weight loss and dehydration vary widely across disease states and stages. Weight loss is associated with greater medical morbidity and shorter survival for the majority of cancers. Detecting weight loss among dying patients can be confounded by the presence of anasarca. Nonetheless, it has been reported that nearly all cancer patients have significant weight loss at the time of death (204).

## Causes

Sources of dehydration are common in terminally ill patients. Probable causes depend on whether the patient has hyponatremic, hypernatremic, or isotonic dehydration. Hyponatremic dehydration arises when sodium loss exceeds water loss and occurs most frequently with water, rather than food. Common causes include volume depletion, anorexia, nausea, and vomiting. Overuse of diuretics, salt-wasting renal conditions, third spacing, and adrenal insufficiency are also common sources of sodium loss (396). Hypertonic dehydration occurs if water losses are greater than sodium losses. Fever is a common cause, as well as water loss through lungs, skin, and insufficient oral intake. Isotonic dehydration results from balanced loss of water and sodium. It has been suggested that the majority of patients with advanced disease have this type of eunatremic dehydration (397).

Nutritional deficiency may arise from anorexia as previously discussed. In addition to suppressed appetite, altered mental status, malignant GI obstruction, immobility, dysphagia, odynophagia, and uncontrolled cough and hiccups can interfere with adequate nutritional intake.

## Assessment

Clinical assessment for dehydration should include screening for mental status changes, thirst, oral/parenteral intake, urine

output, and fluid loss. Patients may or may not experience thirst. On physical examination, evidence of reduced skin turgor, dry mouth, and postural hypotension should be sought. Laboratory evaluations for hematocrit, serum sodium, blood urea nitrogen, and creatinine should be obtained if the workup is contextually appropriate. Urine osmolarity may also be useful.

Evaluation for reduced nutritional intake should include questions regarding diminished appetite, pain with eating, choking or coughing with swallowing, early satiety, altered or diminished sense of taste, and regularity of bowel movements. Oral pain can be associated with thrush, graft versus host disease, osteoradionecrosis (in head and neck cancer patients), mucositis, osseous metastases to facial bones, herpes zoster infection, and neuropathic pain syndromes. Imaging studies may be required to confirm the presence of malignant involvement of the GI tract.

### Treatment

There is no evidence to support enhanced comfort through the use of supplemental hydration (398). Clinical studies have produced mixed results (399,400). Proposed reasons for and against providing supplemental fluids related to control of neurocognitive symptoms are listed in Table 69-6 (401). Reduced intravascular volume can lead to the accumulation of opioid

and other pharmacological byproducts, which may aggravate undesirable side effects such as confusion, sedation, myoclonus, and seizures. Dehydration can place patients at increased risk for bedsores, constipation, and xerostomia. However, there are equally compelling reasons to question the benefits of supplemental hydration (see Table 69-6).

A standard goal for fluid is 1,500 to 3,000 mL, or eight to ten glasses of water daily. Offering fluid at regular intervals merits a trial. Sports replacement fluids may be preferred by some patients and can correct hypotonic dehydration. Nonoral routes of fluid supplementation include parenteral administration, proctoclysis, and hypodermoclysis. Use of an NG tube for the introduction of enteral fluids is discouraged because patients may inadvertently extubate themselves, and NG tubes can be a source of considerable discomfort (402). Rehydration by proctoclysis involves the use of an NG tube placed rectally (398,402). Tap water or saline can be instilled at a rate of 100 to 400 cc/h. Treatment should be initiated at a rate of 50 to 100 cc/h and gradually increased with close monitoring for rectal leakage. Although this approach has been shown to be safe, economical, and effective, the majority of patients prefer hypodermoclysis. Hypodermoclysis refers to subcutaneous fluid infusion through needles inserted in the tissue of the abdomen or thigh (398,402). Hypotonic or isotonic solutions are generally used with or without hyaluronidase or corticosteroids. An infusion of 100 mL/h is usually well tolerated. Once 1,500 mL have been instilled, an alternate administration site should be chosen.

Nutritional therapy is aimed at improving metabolic status, body composition, functional status, and QOL. The literature offers insufficient evidence for enhanced survival in terminally ill patients (403). Artificial nutrition can be delivered enterally or parenterally. Whenever possible, the enteral route of feeding is preferred. Slow initial rates of 10 to 20 mL/h should be used. If tolerated, rates can be increased by 10 mL every 8 to 12 hours until full flow rates are reached. For terminal patients incapable of enterally absorbing or assimilating nutrients, total parenteral nutrition can be prescribed. Whether the enteral or parenteral route is used, basal metabolic requirements can be calculated using the following Harris-Benedict equations (404).

$$\text{BMR for men} = 66.4730 + (13.7516W) + (5.0033H) - (6.7550A)$$

$$\text{BMR for women} = 65.5095 + (9.563W) + (1.8496H) - (4.6756A)$$

where W denotes the weight, H the height, and A the age.

Ongoing vigilance must be maintained for evidence of infection in patients receiving total parenteral nutrition. High prevalence rates have been reported, particularly in patients with advanced disease (405,406).

### EXERCISE AS PALLIATION

There are excellent reasons to believe that structured exercise may significantly benefit patients with advanced disease and decelerate their functional decline. First, exercise ameliorates a

variety of symptoms that constrain patients' function including dyspnea and fatigue (407). Controlled trials of aerobic conditioning at 55% to 70%  $\text{VO}_{2\text{max}}$  in cancer patients both who are receiving and who have completed chemotherapy demonstrate significant benefits not only in symptom burden but also psychological well-being and QOL (408–411). A strong association between exercise and enhanced mood has been reported in many disparate cohorts from a wide range of disease states (412–414). Benefits across multiple symptoms and QOL domains have been reported in cohorts of cancer and AIDS (415) patients, as well as those with advanced lung (416) and heart disease (417).

Despite the many compelling reasons to consider exercise in symptom alleviation, skepticism has been raised regarding the ability and willingness of patients with cancer and other types of advanced stage illness to consistently participate in exercise programs (418,419). The encouraging work of Yoshioka (11) suggests that even hospice patients can make substantial gains in mobility through conventional physical therapy (PT) approaches, yet the low-level mobility activities employed in PT are generally distinct from conditioning activities delivered for symptom alleviation. Limited pilot data suggest that patients with advanced cancer and limited life expectancy benefit from circuit training through enhanced physical performance and reduced fatigue (420). However, although the investigators selected patients with Karnofsky Performance Status more than 60 and estimated prognoses of 3 to 12 months, only 63% of patients approached agreed to participate and 54% of participant were able to complete the study (421). A literature review demonstrated that disappointing, approximately 50%, uptake and completion rates characterize many exercise studies targeting cancer populations, not solely those with advanced disease (422). Neuromuscular electrical stimulation has been suggested as a possible alternative to active participation in exercise protocols as a means of preserving functionality in patients with advanced cancer (421). Supportive data are limited to a promising case study (423).

Efforts to assess receptivity to function-oriented therapies among patients with metastatic cancer suggest that interest is high and correlates with self- and clinician-rated functional limitations (11,424,425). Various barriers have been identified as constraining patients' ability to actualize their interest and begin regular structured exercise including transportation, cost, winter weather, and the demands of cancer treatment (425,426). Clark et al. reported that fatigue was the most frequently listed barrier to physical activity among patients with advanced cancer receiving chemotherapy (425).

The importance of structure and support is suggested by reduced adherence levels following termination of experimental exercise protocols in cancer patients (427,428). It is reasonable to assume the patients with advanced diseases may be in considerably greater need for ongoing support and supervision in order to adhere to exercise. Thus far, creative approaches to providing structure for exercise that avoid heavy time and travel burdens have not been developed. Since patients identify time as a significant barrier to exercise, home-based programs

may be a promising option for future development (425). One study failed to detect a difference between exercise interventions delivered in supervised and self-directed fashions (429).

## CONCLUSION

One factor that may foster the integration of rehabilitation and palliative services is the striking parallel between their general therapeutic paradigms. Both disciplines encourage creative problem solving, whether for functional, psychological, or physical difficulties in the interest of improved function and QOL. The desire to help patients live well to the fullest of their abilities galvanizes palliative and rehabilitation teams in a unified purpose. Both disciplines acknowledge the importance of a holistic integration of disparate disciplines so that the unique case-by-case challenges may be met. It is hoped that this common ground will serve as a foundation for building a body of clinical and academic rehabilitative expertise unique to the palliative patient.

# Evolution of Biofeedback in Physical Medicine and Rehabilitation

Biofeedback (BF) can be defined as the use of instrumentation to reveal covert physiological processes via user detectable cues, such as visible light and audible tone, for appropriate response shaping. The BF loop consists of a BF machine and user, and as necessary an instructor/trainer/clinician. Ultimately, the machine functions as an extension of human sense to record and display the internal physiological signals or events; the user, armed with feedback information, acquires the skills to control the physiological response toward desired state through mind-body self-regulation.

Biofeedback became recognized as an alternative or adjunct medical tool in the 1960s and has been applied to psychotherapy, physical medicine, sports medicine, incontinence treatment, pain management, and more recently, in the management of other behaviors associated with pediatrics and oncology. This presentation is directed toward rehabilitation medicine in general and the control of movement in particular.

In physical medicine and rehabilitation, the initial BF application arose from diagnostic and research work in electromyography (EMG) (1), which became the most practical BF form in the field. From the 1960s to the 1990s, most clinical and experimental BF applications used EMG, joint angle, position, force, or pressure to reeducate the control of muscles, joint, and balance in patients with various neuromotor deficits. The outcomes provided concrete evidence that objective neurological signs and symptoms can be altered, particularly in patients with upper motor neuron paralysis and spasticity resulting from brain damage (2–5). However, the initial BF applications did not correlate well to patients' motor function improvement. This observation may be partly due to the early "static" BF training paradigm, in which patients received BF training in a static posture or during nonfunctional related movement. Since the mid-1990s, several experimental studies, inspired by the concept of task-oriented training for motor functional recovery, have transformed BF interventions into functional task training that might employ feedback principles (6–11). In addition, recent technological advances have further promoted this new direction. The emergence of novel sensors, advanced signal processing and control, remote communication, and three-dimensional (3D) displays in BF applications will further leverage the influence of BF therapy in physical medicine and rehabilitation.

The purposes of this chapter are to (a) provide a general review of the early experimental and clinical BF applications in physical medicine and rehabilitation and (b) introduce recent developments in rehabilitation technologies and applications toward task-oriented BF interventions. Readers are encouraged to keep in mind that some of these new technologies and applications are still in their infancy; continuous efforts are demanded to establish effective training protocols and outcome measurements and in evaluating these new BF technologies and interventions before reaching definitive conclusions.

## TRADITIONAL BIOFEEDBACK IN REHABILITATION

### Methods of Biofeedback

#### Electromyographic Biofeedback

The electromyographic signal or EMG is an electrical manifestation of muscle activity and an effective window to inspect neuromuscular control system. In BF retraining, EMG is the most used form to down-train hyperactive muscles or up-train flaccid or weak muscles in patients with various sensorimotor deficits (12–14), thus further improving patients' control over joint. Usually, bipolar surface EMG electrodes are placed on one or two targeted muscles. The sensed signals are digitally sampled at 1,000 Hz or higher rate. The raw signal, the integrated EMG, or the frequency of EMG is then translated into simple acoustic and visual signals (e.g., lights and audio cues) or graphic computer displays (Fig. 70-1). Patients receive the feedback in a quiet environment and mostly in a static posture. Noise is held to a minimum, and visual distractions avoided. Special uses of intramuscular EMG (IMG) BF include attempts at training deep inaccessible muscles, paralytic muscles, muscles separated from the skin by considerable adipose tissue, or muscles that are not easily isolated by surface electrodes. IMG signals are commonly recorded by invasive, indwelling fine-wire or concentric needles and sampled at 10 kHz or higher rate.

#### Joint Angle Biofeedback

Joint angle BF can be efficient for improving joint movement control (15), even more than EMGBF (5). When the active joint motion is presented but limited in patients with neuromotor deficits, compared to EMGBF, joint angle BF might

**FIGURE 70-1.** Basic block diagram of an electromyographic biofeedback device. LED, light-emitting diode. (Reprinted from Basmajian JV, ed. *Biofeedback: Principles and Practice for Clinicians*. 3rd ed. Baltimore, MD: Williams & Wilkins; 1989, with permission.)

be promising for effective and expeditious recovery of joint control. In addition, angle BF is indicated when the goal of training is the regulation of joint movement, such as correction of genu recurvatum (16,17) or the control of movement with appropriate timing and coordination (5,6). Moreover, joint angle BF may be used when the muscle that must be monitored is inaccessible or difficult to isolate. Electrogoniometers reliably reproduced the clinical measurements of joint angle (11); they have been widely employed in angle BF devices. Other applied sensors include mercury tilt switches and gyroscopes. The quantified joint angle is fed back to the patient during single joint movement for targeted angle tracking (15), or during multijoint coordinated movement, such as gait (6,11).

### Pressure or Force Biofeedback

Force or pressure monitoring may be indicated when information concerning the amount of force being transmitted through a body segment or assistive device is desired. Force/pressure sensitive platforms whose applications are described in more detail later in this chapter (see “Balance Rehabilitation”) are often used for retraining of balance (18). As shown in Figure 70-2, a patient with balance control deficits stands on a force plate that measures the ground reaction force or pressure and/or moments in three orthogonal directions under the feet. The derivative of force or pressure measurements such as center of force (COF) (18), center of pressure (COP) (19–22), or center of gravity (COG) (23–25) is displayed as a cursor projected on a two-dimensional (2D) screen in front of patients. The goal of the patients is to move the cursor to a desired

**FIGURE 70-2.** Platform-based force/pressure biofeedback for balance retraining.

location or within a targeted area (18). Some commercial force platforms are also equipped with motors that can translate or tilt the platform for balance perturbation (26,27). Force BF training under conditions of posture perturbation have been applied to permit older adults at risk of fall to experience strategies to abort falls (14,24,28). Most of applications feedback the COP cursor instantaneously and such training has been reported to induce both favorable (the amplitudes of the horizontal motion of the COG are diminished) and unfavorable features (the vertical difference between the COG motion and the COP trajectories are enhanced) for reacquisition of balance control (20). Findings from one study suggested that delayed visual feedback of the COP cursor exceeding 600 ms can significantly suppress the unfavorable features and retain the beneficial aspect of COP BF training (20).

Recent sensor technologies, such as insole pressure sensors (29) and portable pressure walkways (30), allow force/pressure BF training in ambulation. All these devices can display the pressure distribution and the COP in real time. In addition to the force measurement using force plates, the loading force or pressure measured by load cells in assistive devices such as canes (31) or prostheses (32) has been used to train patients' body-weight loading on the impaired limbs during ambulation.

### Miscellaneous Techniques

Beyond EMG, joint angle, and force, many other parameters have been monitored for miscellaneous BF applications in

neuromotor rehabilitation. For example, BF of step length (7), knee-to-knee distance (8), and step timing (9) were applied to correct abnormal gait pattern. Trunk acceleration was the BF parameter for stance balance training (33). The applied BF equipment ranged from a simple mirror to expensive motion tracking cameras.

Some studies conducted BF training using multiple data sources. For example, studies coupled EMGBF with joint angle BF and trained stroke patients to control the joint to a desired position by increasing the recruitment of agonist and/or reducing the muscle activity from antagonist (6,14). The risk in using multisource BF is that multiple quantified feedback cues might overload patients' perception and confuse patients; careful design of feedback cue displays is essential for successful BF applications.

## Biofeedback Modalities

### Visual Feedback

Visual displays available with BF devices include banks of lights, liquid crystal display (LCD), meters, oscilloscopes, or computer monitors. The visual display can be binary (0/1 in value or light on/off), digital (integral numbers), or continuous (signal waves or value bar).

The sensitivity scale in the visual display should be determined by the goals for the BF training. In EMGBF, if the EMG electrodes are properly applied, it is theoretically possible to obtain accurate readings of activity as low as 1  $\mu$ V, but such low integrated levels are important only during generalized relaxation training. Retraining patients with musculoskeletal weakness (e.g., the quadriceps after meniscectomy) requires a feedback device with comparatively low sensitivity settings because such patients often learn to generate several hundred microvolts of integrated EMG during isometric or isokinetic contractions. Most contemporary feedback displays have software that adjusts the range of sensitivities as the patient changes his or her muscle output capability with an intent of providing a continuous range that can be visualized and manipulated by the patient within his or her training sessions.

Caution must be exercised when trainees have visual deficits secondary to brain injury. Furthermore, when the BF training involves activities such as gait, visual feedback should be avoided or kept minimal because vision is largely occupied to guide motor coordination.

### Audio Feedback

Many commercially available devices offer auditory feedback in the form of a tone, buzzer, click, or a combination of these possibilities. Similar to visual feedback, the audible feedback could be binary, discrete, or continuous. In devices with binary display, a monotone buzzer is heard only when the patient achieves a specific feedback value preset by the therapist. In EMGBF, a low threshold setting may be used in training for recruitment of activity above a given level in a weak or paretic muscle. Once the patient reliably exceeds this level, the threshold is raised progressively. This technique is often referred to as shaping. The reverse shaping strategy to reduce integrated

EMG levels (i.e., reduction of resting hypertonus) also may be used. Additionally, binary auditory feedback is useful for BF therapy set in the activities of daily living (ADL); the auditory tone is given only if needed so that users can concentrate on the daily activities most of the time. The device with discrete audible feedback maps more than two physiological states into sounds with different pitch, duration, or loudness. The continuous auditory feedback directly displays the sampled physiological signal. For example, surface EMG was directly transformed into a sound. When the muscle is activated, the audio components increase in intensity and pitch, which can be resolved by patients as effective feedback required to regulate the muscle activation level.

A number of studies compared the influence of auditory display to that of visual feedback during BF training. The auditory cue was reported to have more patient acceptance than the visual feedback when the BF training was carried out in ambulation (11). Another study found that audio BF had larger effects on reducing COP displacement while visual BF had larger effects on reducing trunk sway, which suggests that the two BF modalities may encourage a different type of posture sway strategy (34).

### Tactile Feedback

Applied tactile sensation arises from a simple mechanical vibrating stimulator attached to the skin. By modulating the vibration frequency and amplitude, the vibrating stimulator feeds back the sensed physiological signal to the user (35,36). Vibrotactile feedback is safe, frees the user from having to maintain visual attention to the feedback cues, and presents minimum distraction to others. However, results from previous studies indicate that while the user could easily adapt to the tactile stimulation, the tactile biofeedback cues were ignored as participants engaged in ADL (36). These observations may have resulted from the relatively smaller number of reported studies using tactile BF compared to the use of visual or auditory cues.

## Scientific Basis of Biofeedback

The mechanisms underlying successful use of BF are still unclear. In physical rehabilitation, BF may enhance sensorimotor integration because this approach highlights utilization of sensory cues that inform patients about consequences of their movements while allowing them to develop adaptive strategies for motor learning and recovery.

### Neurological Basis of Biofeedback

Wolf and Binder-MacLeod (37) have asked, "How do patients process feedback information? What factors account for the patient's ability to gradually become less dependent upon artificially induced information signals after failing to achieve significant gains using conventional rehabilitation procedures?" Previous studies demonstrated that the BF therapy was associated with cortical reorganization (38,39). Specifically, fMRI studies have shown that following biofeedback training to enhance ambulation following stroke, enhanced activation during

controlled knee flexion extension was seen in the ipsilesional primary sensorimotor cortex. The extent to which such changes are manifest with biofeedback neuromuscular reeducation of different joints and for different diagnoses requires considerable investigation. The two possibilities suggested many years ago by Basmajian (12), either an auxiliary feedback loop to recruit existing cerebral and spinal pathways or the development of new pathways, are worthy candidates for further study.

Nonetheless, the central nervous system uses a multitude of internal modulatory networks. The role of somatosensory or other subcortical areas, and the basal ganglia should not be underemphasized; their timely activation make voluntary movements meaningful. Proprioception, tactile, auditory, and visual inputs are harmonized into the controls, as is the cerebellum. Therefore, damage resulting from external and internal trauma to area 4 of the cerebral cortex may spare pathways that are primarily engaged for reacquisition of skilled movements, or they may spare redundant pathways that EMGBF training can bring into play. Wolf (40) has further speculated three detailed conceptualizations: (a) override: visual or audio feedback may activate the somatosensory cortex by entering at a level higher than the level of damage; (b) bypass: an appropriate feedforward system can be established via the brain stem motor nuclei; (c) repetition with existing neural circuitry: central synapses previously unused in executing motor commands may be activated by visual and audio feedback. As such, continued training may establish new sensory engrams and help patients perform tasks without feedback.

Plasticity and relearning by the brain should be thought of as a more complex phenomenon than usurping function by specialized areas of the neighboring cortex. There is evidence from rat stroke models that changes in dendritic architecture or density of synaptic boutons are associated with motor relearning, provided that the task practice is repetitive and challenging (41,42). Whether the BF training employs and in turn reinforces these new neural connections is unclear.

### Placebo Effect

Basmajian (43) addressed placebo factors that are powerful in all therapies, including BF alleged “cures.” Therefore, the placebo effect needs to be understood, accepted wisely and gratefully, and rebuffed. In fact, many clinical studies, especially those based upon pharmacological interventions, question the impact of the intervention if improvements are not in excess of 30% beyond control values or have not been powered adequately to determine a “minimally clinical important difference” (44,45). A deliberate placebo may be best used in double-blind research studies, or rarely as a therapeutic test.

## Biofeedback Applications in Physical Medicine and Rehabilitation

### Stroke Rehabilitation

A major application of biofeedback in rehabilitation hospitals and outpatient clinics lies in the treatment of patients following stroke. The National Institute for Health (46) lists stroke as the number one cause of adult disability in the United

States. Approximately 780,000 people experience a new or recurrent stroke each year (47). Motor dysfunction after stroke may be characterized by muscle weakness, abnormal muscle tone, abnormal movement synergies, and lack of coordination during voluntary movement. Restoring the neuromuscular control in patients with stroke is essential to further improve their motor functions. EMGBF is a useful tool for reeducating neuromuscular control in stroke rehabilitation (3,4,48–52). Other forms of BF, such as force and joint angle BF, have also been applied, but with less frequent use.

### EMG Biofeedback for Upper- and Lower-Extremity Rehabilitation

Wolf et al. (37,53) investigated patient characteristics that may affect the outcome of EMGBF training of hemiplegic patients. The presence of proprioceptive loss appeared to diminish the probability of making functional gains in the upper limb. Age, gender, hemiparetic side, duration of stroke, previous rehabilitation, and number of training sessions did not have a significant effect; patients should not be excluded from feedback training based solely on either age or length of time since their stroke. However, the optimal time for introducing BF appears to be the same as for any rehabilitation efforts: fairly early.

In EMGBF, a practically standard training scheme has been adopted. Detailed EMGBF training protocols for stroke rehabilitation can be found elsewhere (54). Scientists at Emory University have conducted a series of studies to implement EMGBF for stroke rehabilitation. The belief that neurological patients should first have hyperactive muscle down-trained motivated the application of EMGBF to spastic muscles initially. Relaxation training was applied on patients when they were at rest, during passive movements, during distractive movements, and then during shortening contractions. Once the muscles were relaxed, attention was directed toward the antagonist muscles, the ones that are usually weak and need to be up-trained in EMGBF. Last, the coordination of both muscle groups must be trained for efficient joint control. Ultimately, this BF training paradigm was put into a functional context. While this paradigm did yield significant improvements (3,4,55,56), the greatest predictor for ultimate success in applying EMGBF was in the patients’ abilities to demonstrate small amounts of active extension at the elbow, wrist, and fingers (14). In fact, these observations served as the inclusion criteria for the first forced use and constraint induced movement therapy studies (57–60).

EMGBF for upper-extremity rehabilitation starts from the shoulder joint, followed by elbow, wrist, and hand (54). EMGBF training of pronation and supination of the forearm is difficult because of the cross talk between the EMG activity from the pronators and supinators and other EMG present in the forearm; EMGBF may be combined with angular BF in cases of severe spasticity or flaccidity. Targeted training of the lower limb is simpler than that of the upper limb. Training of the lower limb need not follow the proximal-to-distal progression for the upper limb. The primary functional goals are improved ambulation and to develop a relatively limited

number of stereotyped patterns used during ambulation. One of the important areas of EMGBF training was for the treatment of foot drop caused by paralysis of the ankle dorsiflexors and spasticity of the plantar flexors (2,61). Other training protocols involve training of multiple joints simultaneously to coordinate, such as the training of hip and knee extension critical for the gait stance phase, hip flexion with knee extension important during the terminal swing phase of gait, and hip extension with knee flexion (54).

The current view that the task-oriented repetitive training is essential for motor functional recovery motivates clinicians and scientists to conduct BF training when patients are walking (6–8,17,62–64). BF retraining during ambulation focuses on specific gait timing, because the coordination of muscles or joints depends on gait phase. In this case, a gait event detection system such as footswitch is essential (6). Continuously monitoring the gait performance, such as gait symmetry, weight loading, or muscle recruitment has also been reported (7,62). Auditory warning buzz provides discrete feedback only if the monitored parameter is out of the desired range. The clinical effect of BF training for stroke rehabilitation is still controversial, the detail of which is summarized later in this chapter (see “Randomized Controlled Trials and Meta-Analyses”).

### Balance Rehabilitation

Another major application of BF in stroke rehabilitation is the training of balance control (23,25,65–68). Roughly 40% of stroke patients will experience a serious fall within a year after having a stroke (69). Unsteadiness during stance, asymmetric weight loading, and decreased ability to move within a weight-bearing posture have been reported among stroke survivors. Nichols gave a thorough review and update on force platform BF for balance retraining (18). The training protocols address three components of the function: steadiness, symmetry, and dynamic stability. In retraining of postural steadiness, stroke patients stand on a force plate, wearing a fall arrest harness. Patients are required to keep the cursor representing COF or COP within a narrow range while they sway the body weight. To improve the control of postural symmetry, the force BF training progresses from static standing to dynamic movements, such as sit-to-stand transfers and stepping in place. The percentage of weight bearing on the nonparetic and paretic leg is quantified and displayed visually and audibly (19,65,70). The goal of trainees is to equalize the weight loading on each leg. The training of postural steadiness and symmetry resulted in the reduction in weight-bearing asymmetry (65,70–72); however, stroke patients failed to reduce their spontaneous sway amplitude and did not improve on functional measures (65,70). The dynamic postural control will be last trained. The patients are instructed to voluntarily move the COP/COF cursor from one target to another in different directions accurately without falling (21,23). The capability to transfer body weight and adopt a different stance position is a prerequisite for safe mobility (73). Hence, training of dynamic stability is thought to have important links to the function (18), but no strong evidence has been found to support this contention.

### Spinal Cord Injuries

Spinal cord injury (SCI) results in varying degrees of weakness and sensory loss at and below (i.e., caudal to) the site of injury. The motor deficits may be represented as muscle weakness and limb paralysis, spasticity, lost of normal bladder control, and breathing difficulty.

The primary goals for interfacing patients with SCI with EMGBF are much the same as those outlined previously for stroke patients. First, attempts are made to reduce hypermotor responses to induced length changes in spastic muscles. Such hyperactive behavior of spastic muscles may occur during spontaneous episodes of clonus or during induced clonic seizures, when the lower or upper extremity responds to various tactile stimuli. Once the patient can reduce such responses in supine, sitting, and ultimately standing postures, efforts are directed toward recruitment of weak muscles.

In patients with paraparesis following SCI, EMGBF training at the Emory University enabled many patients to increase the speed at which they ambulate and to reduce the number of required assistive devices. For patients with tetraparesis and obvious residual voluntary movement, feedback combined with an exercise program facilitated active range of motion (ROM) and improved upper-extremity function. Feedback may be beneficial for these patients because the modality may be easily incorporated into exercise programs with immobilized patients during the acute phase of injury; it provides immediate information to the patient concerning the level of voluntary muscle activity; and, by so doing, this modality may help patients obtain spatial and temporal summation of muscle potentials leading toward increased contractility, and therefore preparing the patient for a more vigorous therapy program. However, in cases in which little activity could be observed among chronic SCI patients, feedback provided little or no significant benefit toward restoration of function (74). Other clinical trials demonstrate controversial results on the effects of EMGBF for patients with chronic, tetraparesis secondary to SCI. One study using a pre-post experimental design found that EMGBF was helpful in increasing voluntary muscle recruitment in long-term spinal injured patients (75), while another similar study found no significant improvement (76).

In addition to the regular EMGBF training described above, the study groups at the Emory University have conducted a series of studies to investigate whether EMGBF can be applied to reduce the spinal stretch reflex in healthy and neurological patients (77–79). After 2-week training, all the SCI patients exhibited significantly reduced spinal stretch reflex. However, the value of this observation in SCI rehabilitation and clinical application requires further investigations.

### Cerebral Palsy and Traumatic Brain Injuries

Early EMGBF applications monitored the spastic muscles in patients with cerebral palsy (CP) or traumatic brain injury (TBI) (80–84). In the study of Neilson and McCaughey (80), a progressive muscle relaxation procedure was adopted for the biceps brachii muscle. EMGBF was employed to down-train the sensitivity of tonic stretch reflex. Four young

adults with CP reduced the involuntary muscle activity and stretch reflex sensitivity. However, only one athetotic patient improved voluntary joint control as a consequence of reducing the amount of involuntary arm movement. EMGBF was also applied to down-train the gain of stretch reflex for correction of muscle contracture (81,82). Although patients with CP significantly decreased the stretch reflex, the contracture was not altered (82); thus, EMGBF might only be useful for preventing the progress of muscle contracture.

With the view that the deficits of motor function in CP patients are more related to deficits in strength and control than spasticity (85), the recent applications of EMGBF shifted attention to the up-training of muscle activity, muscle synergy, and joint control. A successful application of EMGBF in patients with CP is seen in the retraining of ankle control (86–89). EMG from either plantarflexor (86,89) or dorsiflexors (87,88) was measured and displayed. Patients were trained to increase the muscle activity or to improve the muscle or joint control during gait cycle. The results of these studies were encouraging; the voluntary muscle control, the ankle active ROM, and the functional gait parameters were positively affected by EMGBF training. Bolek (90) developed a multiple-site performance-contingent feedback to treat motor dysfunctions in patients with CP. The applied EMG sites were customized to each patient who learned the synergy of multiple muscles for improved joint control. Fourteen of the sixteen children with CP improved the control of multiple muscle recruitment patterns during the treatment.

Head position control using positional BF (91,92), control of drooling using EMGBF (93), and trunk sitting posture control by angular (36) or pressure BF (94) have been used with CP patients, but formal studies are sparse.

### Multiple Sclerosis

Multiple sclerosis (MS) causes a variety of sensorimotor dysfunction, including muscle weakness, abnormal muscle tone, difficulties in coordination and balance, problem in speech and swallowing, fatigue, change in sensation, and bladder and bowel control difficulties (95).

Ladd et al. (96) applied the EMGBF and an antispasticity drug (dantrolene sodium) on the soleus muscle in MS patients because it was the most spastic. This study found that the ability of patients to establish voluntary control over fine neuromuscular activity in the spastic soleus was considerably inferior to that of able-bodied subjects, but this ability was significantly improved to near that of able-bodied subjects by Dantrolene. Basmajian believes that the abnormal fatigue induced by any form of training reduces the usefulness of EMGBF for motor retraining. In selected patients, it may be useful in training muscle relaxation of mild spasticity and general tenseness. For moderate and marked spasticity, he does not advocate EMGBF, preferring one or another of the specific antispasticity drugs (97).

Head position BF training and self-stabilization of head position during treadmill walking was compared between able-bodied and MS subjects (98). Patients with MS had poor

head control compared to healthy subjects, which may partially explain the dynamic balance problem of patients with MS. Both self-stabilization of head position and BF training reduced the amount of head motion; no difference between interventions was observed. The training effects in MS patients, however, did not transfer to the dynamic balance control in the Timed Up and Go test.

Pelvis floor EMGBF has been applied to MS patients for the treatment of incontinence or constipation (99–102). EMGBF was beneficial to alleviate some of the symptoms of lower urinary tract dysfunction when combined with other conventional training (100) and was especially effective in MS patients who had lower disability and a nonprogressive disease course (101,102).

### Dystonias and Dyskinesias

Ignoring the many conflicting theories of etiology that provide no clear guides to therapy, we briefly discuss here a number of movement disorders that have responded well to behavioral therapy featuring EMGBF. They present themselves mainly in isolated muscle groups; spasmodic torticollis is the best example (103–106), but also included are the rarer blepharospasm (107–109), hemifacial spasm (110), writer's cramp (111–115), and severe torsional dystonias of the torso (i.e., malignant dystonia musculorum deformans). Many brief case studies have been reported. The most thorough studies of many patients successfully treated with EMGBF combined with other behavioral techniques were reported by Brudny et al. (116) and by Cleeland (103).

### Peripheral Nerve Denervation

Facial palsy causes weakness or paralysis of the facial muscles, accompanied by other complications (117). Synkinesis is one of the complications and is an abnormal involuntary associated facial movement during blinking. The underlying mechanism of synkinesis is inappropriate reinnervation of the regenerating facial nerve fiber to the facial muscle (118).

EMGBF is an efficient rehabilitation intervention for patients with facial palsy (118–125). Results from studies have shown that after EMGBF training, there was substantial improvement in facial symmetry and voluntary functions. Moreover, EMGBF was reported to be useful to further improve the facial function in patients undergoing facial anastomosis surgery (123–125).

### Polyneuropathy and Peripheral Neuropathy

Patients with diabetes might develop sensory neuropathy that compromises proprioception. BF devices function as a bypass to close the motor control loop for sensorimotor integration (24,126). Patients with sensory neuropathy demonstrated dysfunction on balance control and increased rates of fall (127). A controlled trial tested BF of COG for balance retraining against conventional therapy and found that BF is more efficacious (24). Walker et al. (126) developed a pressure BF device with audio feedback, which was applied to warn the excessive pressure on the user's foot and therefore prevent neuropathic ulcer.

### Pain Management and Biofeedback

Related disciplines, especially psychotherapy and pain clinics, widely use EMGBF for relaxation, both general and specific (54). In addition, skin temperature feedback training is used for treating pain conditions normally not seen by rehabilitation clinicians (e.g., migraine) with generally good results (54). While these approaches are exciting, the voluminous literature available is overwhelming and beyond the scope of this chapter. Interested readers are encouraged to explore some contemporary but excellent references (128,129).

Acute and chronic back pain treatment with targeted surface EMGBF, as an adjunct to conventional excises, has shown positive effects on the strength of lumbar paraspinal muscles (130,131). Recently, advances in the ultrasound technique make the noninvasive measurement of deep muscle activity in real time possible. Studies employed ultrasound image-based BF to down-retrain the deep lumbar muscle of patients with lower back pain and found promising effects of the intervention (132,133).

### Orthopedic and Prosthetic Rehabilitation

Joint angle BF devices have been successfully used in retraining of hand function after reparative surgery of traumatized fingers and their motor nerves (134). The feedback goniometers have been developed that are worn on the hand during exercise and therapeutic activities. These devices supply a threshold feedback signal when a predetermined joint angle is attained. Clinical trials indicate that many patients in a comprehensive hand rehabilitation program after injuries or corrective surgery will improve somewhat more in active ROM if they use feedback goniometers while exercising. Similar joint angle BF goniometers have also been used for training knee ROM in patients post total knee arthroplasty (11).

EMGBF can be helpful in the treatment of musculoskeletal disorders (135–137). For example, a controlled study demonstrated that BF alone is more effective than electrical stimulation alone in the recovery of the peak torque or force of extension of the knee after anterior cruciate ligament surgery (136). A more recent controlled trial also found that EMGBF, compared to the conventional therapy, was an effective training modality in improving quadriceps muscle strength after arthroscopic meniscectomy surgery (137).

### Randomized Controlled Trials and Meta-Analyses

Randomized controlled trials (RCTs) are the gold standard prerequisite to obtain a statistically validated conclusion because RCTs eliminate all forms of spurious causality (40). Previously conducted controlled trials tested BF plus conventional physical therapy (CPT) against CPT alone (4). For chronic stroke patients, EMGBF, when used as an adjunct to CPT, resulted in improvement in upper-limb ROM and muscle strength. The authors emphasized that EMGBF is an adjunctive and not a total therapy.

Meta-analyses of BF studies by three separate study groups have yielded conflicting conclusions, ranging from “effective tool for neuromuscular reeducation in the hemiplegic stroke

patient” (138) to “[do] not conclusively indicate superiority” (139) and “do not support the efficacy of BF in restoring the ROM of hemiparetic joints” (140), with a caution that a type II error may be masking “an important clinical benefit.” As is the case with so many meta-analyses, the reason for the diverse results might reside in use of different criteria for data inclusion and incongruities in the specification of end point measurements. Schleenbaker and Mainous (138) included studies with a non-RCT, while other studies only considered RCTs (139–141). Some meta-analyses selected studies that assigned no therapy to the control group (138,140), which resulted in the increase of the effect size of biofeedback therapy. The end point measurements in meta-analysis studies were diverse: some focused on functional scores and the others compared non-functional related parameters such as passive joint ROM, which contribute to the divergent conclusions among the meta-analysis studies. In general, EMGBF yielded positive effects if the outcome measurement was related to control of specific muscle and joint that had been trained; however, the effects of EMGBF did not correlate well with motor function recovery. Another confounding factor contributing to the inconclusive meta-analyses is the combination of upper-limb results (less favorable) with lower-limb results (more favorable).

Another recent study reviewed 26 BF studies for upper-extremity rehabilitation (142). The selected trials were too heterogeneous with regard to the forms of BF (EMG, kinematics, kinetic BF, and feedback of knowledge of result) and the applied patient populations (stroke, SCI, CP, and Parkinson's disease). In addition, the selected studies investigated BF therapy either alone or as an adjunct to different therapy (CPT, functional electrical stimulation (FES), or therapeutic robotic training). The review found neither the evidence supporting the effectiveness of augmented biofeedback on motor function of the upper extremity nor the relationship between the reported effects and patient characteristics or type of BF.

## RECENT TASK-ORIENTED BIOFEEDBACK APPLICATION IN REHABILITATION

### New Concept: From Static to Task-Oriented Biofeedback

The major body of BF research from 1960s to 1990s trained patients with motor deficits in a static position or nonfunctional related movement. Patients were comfortably seated with arm or leg support while receiving visual or auditory feedback of EMG signals. Such a training paradigm elicits localized motor improvement specific to the trained muscles or joint, but it does not transfer to the generalized motor function of paralyzed limb.

As is well known, one major goal of physical rehabilitation is to encourage motor functional recovery in patients with neuromotor deficits, which in turn will improve their quality of life. Contemporary opinion on motor control principles suggests that improvement in functional activities would benefit from task-oriented biofeedback therapy (14,18,52,143–145).

In physical rehabilitation, task-oriented training encourages a patient to explore the environment and to solve specific movement problems. Therefore, effective biofeedback therapy should also reeducate the motor control system during dynamic movements that are functionally goal-oriented rather than relying primarily upon static control of a single muscle or joint activity (14).

Here, we define “static biofeedback” as the BF training performed when patients are in a static position or nonfunctional related joint motion, and “task-oriented biofeedback” as the BF training conducted when patients are performing movement within functional context. The BF training paradigm should focus on “static” first to improve the motor control of specific muscles or joints, followed by “task-oriented biofeedback” for motor functional recovery.

Several studies have performed BF training in a functional context (6–9,14,146), most of which are for gait retraining. The results of existing task-oriented BF studies demonstrate the promise of the task-oriented training concept; however, a task-oriented BF approach faces several difficulties. First, in the functional task training, it is essential to choose the best information or variable to feed back because muscle activity is not always superior (5). The choice of a biofeedback vehicle depends upon the motor control mechanism, training task, and therapeutic goal. Assume that the training task is to reach for and grasp a cup of coffee using only the affected arm. Motor control models suggest that the brain may control limb kinematics by shifting the equilibrium points (147) or creating a “virtual trajectory” of the end point (148), instead of scaling individual muscle activity patterns. Hence, hand trajectory may be a more viable feedback variable than muscle activity (149). Successful reaching and grasping actions also require the control of the finger grip aperture and a hand orientation (150). Therefore, multiple variables should also be considered for biofeedback. Secondly, feeding back multiple indices to patients whose cognition and perception may also be impaired might overload their perception. If the variables are displayed with traditional abstract and quantitative cues, patients may be overburdened by their ability to process multiple sources and become confused and distracted. Designing a BF system that overcomes the “information overloading” obstacle for task retraining is both a technical and conceptual challenge.

### **New Technologies and Applications for Task-Oriented Biofeedback Training**

#### **Information Fusion**

An effective task-oriented biofeedback system requires orchestrated feedback of multiple variables that characterize the task performance without overwhelming a patient’s perception and cognitive ability. A usable system of biofeedback for repetitive task training requires sophisticated technology for sensory fusion.

In physical rehabilitation, a therapist visually observes patients’ motor skills and senses the stiffness of joint by stretching a patient’s limb. The therapist then integrates these observations as well as his/her professional knowledge to determine

the augmented feedbacks that can enhance the patient’s task performance. Information or multisensor fusion is a technology analogous to the therapist’s integration process, which enables the BF machine to be intelligent for determining the state of patient’s task performance with multiple sensed data and some prior knowledge. Therefore, an information fusion is defined as technologies integrating dynamic and volatile flows of information from multimodal sensing sources to determine the state of the monitored system (151–153). The fusion technologies improve the robustness of the machine perception and decision making to monitor or control dynamic systems or those with uncertain states.

Information fusion is essential to narrow the feedback information to patients during task performance. Indeed, it can be as simple as a classifier in BF applications (9). The complex fusion systems are being developed and applied on real-time movement tracking (154); however, the application of these systems to task-oriented BF training is very limited. Here, we want to elicit the awareness of the technology. Although information fusion is a potentially powerful tool for advanced biofeedback systems integrating multisensor information, the challenge of determining the most appropriate and effective means to provide feedback remains.

#### **Virtual Reality**

Task-oriented biofeedback therapy might be more widely effective if the biofeedback cues are multimodal. Plasticity is considered one of the neurological mechanisms of biofeedback therapy; the BF training involving multimodal processes (i.e., vision, auditory, proprioception, etc.) may be efficient and beneficial for motor recovery (155). Additionally, the attractive and motivating cue design is always preferred in the success of therapies because motivation and attention are two key factors to induce neuroplasticity (156). Furthermore, to relieve a patient’s burden for processing multiple biofeedback parameters, design of easy-to-understand biofeedback cues is essential (157).

Virtual reality (VR) is a technology that can be used to design biofeedback cues possessing these desired features. First, VR consists of computerized graphics/animation, sound, and/or haptic stimulation; it not only constructs a virtual environment simulating real functional context but also presents multimodal sensory feedbacks to retrain the user’s task performance. Secondly, VR display is immersive so that patients will be engaged in the biofeedback training. Third, VR-based BF cues are intuitive and easy to understand, because the feedback parameters are displayed via a scene resembling a situation in the real world. For example, compared to the display of quantified joint angles in upper extremity, a virtual arm is an intuitive, integrated presentation that is more easily perceived by neurological patients than multiple abstract, quantified presentations. Additionally, VR and training tasks are easily customized by the computer program. The augmented feedbacks, that is, knowledge of result (KR) and knowledge of performance (KP), are easily incorporated in the VR for efficient motor learning (158).

In VR, visual feedback is accomplished via computer graphics. A stereovision can be created with head-mounted display (HMD) or 3D monitors (159,160). In such systems, the computer generates left and right eye perspective images. Each image is connected to the corresponding monitor in the HMD system or to the corresponding half of the 3D monitor. Some systems generate stereovision by using field sequential stereo in combination with liquid crystal shutter glasses. When the perspective scene generated on the screen is for the right eye, the right lens is clear while the left is opaque. Then the left eye's view is displayed, and the glasses switch the clearness of the lens, creating a clear left lens and opaque right lens (160). The scene can be projected onto walls or a desktop. This kind of system is also called “cave” VR or “fish tank” VR. When applying these immersive systems to neurological patients, however, caution must be exercised because motion sickness, dizziness, and visual problems can occur. A less immersive 2D display that employs screen projected image/animation with depth reference frames can be an alternative choice. Figure 70-3A demonstrates an example of 2D interface designed by Arizona State University for retraining of target-oriented reaching task in stroke patients (161).

Surround sound can provide an immersive environment for auditory biofeedback. Sound is an effective feedback source for temporal information; visual feedback works better for spatial information. Auditory feedback can take the form of pleasant and captive music pieces rather than the simplistic and often annoying tones or beeps in older biofeedback studies. An example of musical feedback design for reaching task is shown in Figure 70-3B (157,161). Music notes within a phrase are distributed spatially along the specified path. When the hand reaches a point along the path where a musical note is located, the corresponding note starts to play. The rhythm of music playback depends on the movement speed. Therefore, patients could “compose” different melodies based on movement pattern and quality. If the movement is spastic, for example, the musical phrase could be distorted by multiple repetitions of one note. Studies have shown that musical feedback can

improve the motor coordination of Parkinson patients (162) and enhance motor learning in a patient with large-fiber sensory neuropathy (163).

Haptic feedback provides users the kinesthetic sensation that is important for task performance (155,164). The position of an end-effector in the haptic device is sensed at very high rates while a user manipulates the end-effector with the hand. The position is sent to a computerized controller, which then decides the feedback force in a haptic interface simulating the interaction between the user's hand and the virtual environment. For example, when simulating the feel of squeezing a rubber ball with a force feedback haptic glove, motors within the glove apply forces to fingers. The farther the user flexes the fingers, the harder the motors push back to feedback the squeeze force. Haptic interfaces allow the patient to interact with and to manipulate a virtual object; such interfaces also encourage patients to immerse themselves in the virtual environment.

The major application of VR-based biofeedback to treat sensorimotor deficits has focused on upper-extremity exercise. Preliminary studies on VR-based biofeedback showed promise for motor functional recovery. Holden et al. (149) utilized VR to train reaching and hand orientation in stroke patients. The virtual “mail” fed back the user's hand position and orientation. The goal of the patient is to reach the slot of a mailbox with correct hand orientation. One of two recruited stroke patients improved Fugl-Meyer (FM) upper-extremity assessment test scores, the performance in a real mailing task, and some motor functions. No improvement was observed in the other patient, however. Later, nine more participants were recruited for further testing (165). All participants showed significant improvement in their FM score, the Wolf Motor Function Test (WMFT) score, and selected strength tests as compared to before the training. The inconsistent results in one patient suggest that a single VR design may not be effective for all stroke survivors. Another study investigated the VR-based BF training for hand rehabilitation in stroke survivors. The training system sensed the finger joint angles from the Cyberglove

**FIGURE 70-3.** Multimedia-based biofeedback system designed by Arts, Media, and Engineering (AME) program at the Arizona State University. **(A)** visual feedback of end-point trajectory in VR and **(B)** auditory feedback of end-point trajectory via music for retraining of target-oriented reaching task in stroke patients. (Reprinted from Huang H, Wolf SL, He J. Recent developments in biofeedback for neuromotor rehabilitation. *J Neuroeng Rehabil.* 2006;3:11, with permission.)

and the applied finger force and the fingertips position from a haptic glove (166,167). The finger joints were displayed using a virtual hand, and the applied grasping force was fed back via a haptic glove (Rutgers Master II). After 2 weeks of biofeedback therapy, patients improved grasping force, finger joint ROM, and movement speed. Three participants showed hand functional improvement. This study focused on training of hand grasping movement and force; however, the major impairment to hand function in stroke patients is motor incapability for hand opening (extension of metacarpophalangeal joints). To improve the effectiveness of hand functional recovery in patients with brain injury, future designs of VR-based BF should emphasize motor tasks that encourage hand opening and wrist extension rather than retraining hand closure.

Biofeedback using VR for the training of lower extremities has been reported recently. An ankle haptic device and a VR system were integrated and tested on individuals post stroke (168). In the training session, patients sat on a medical chair with the impaired foot strapped to the haptic device. The orientation of a virtual airplane or boat fed back the position of ankle, and the haptic device fed back applied force of foot. The training engaged users to allow for repetitive intensive practice. Preliminary result demonstrated that use of VR to augment rehabilitation of individual post stroke merits further study (168). The number of reported VR-based BF studies on gait retraining is relatively small at present, possibly due to the technical challenge of how to process a multitude of information and then present it to patients. A recent study tracked human stepping motion using motion analysis cameras and displayed lower-limb motion in real time via a virtual human, superimposed upon a virtual instructor (169). The goal of the user was to track the movement of the virtual instructor, both the position of joints and the cadency. Any movement error was displayed by the mismatch of two virtual figures. Recruited able-bodied subjects adapted to the virtual instructor while performing the step-in-place task; however, no testing on patients was reported.

### **Biofeedback Therapy Combined With Robot-Assisted Task Retraining**

One inherent limitation of task-oriented BF therapy is that patients with more severe motor deficits cannot participate optimally due to an inability to initiate any functional movement, thus preventing utilization of BF to improve performance. Traditional skateboard facilitated motion using joint angle BF is one of the solutions to ease the limb motion by reducing resisting friction. Recently, rehabilitation robots provide another solution to the problem by providing mechanical assistance to patients' limb movement (170–173).

Robot-assisted rehabilitation training can also benefit from biofeedback. The problem for robot-aided training is that patients with robotic assistance gradually rely on robots and reduce the active involvement in the task learning. Biofeedback encourages self-regulation and motivation and therefore is a useful, complementary tool for the robot-aided therapy. Several research groups have added biofeedback

features into therapeutic robots (170,171). In gait training with Lokomat, which can predefine the pattern of lower-limb kinematics, estimation of self-generated joint torque was displayed in order to motivate patients to produce more force during gait training (171). The combination of robot-aided therapy with task-oriented biofeedback retraining is such an attractive approach for sensorimotor rehabilitation that many new studies can be anticipated.

### ***Wearable Sensors***

Recently, a technology called wearable sensors or sensor network has been introduced into rehabilitation applications, which permit implementation of task-oriented biofeedback anytime and anywhere (174–176). Jovanov et al. (174) designed a wireless body area network that connected data from multisensors on the body to a personal server such as a cell phone or personal digital assistant (PDA). These data can be sent to other computers through a wireless network. This equipment could be used to provide biofeedback during ambulatory settings. Similarly, Sung et al. (176) developed a flexible wearable platform for ambulatory health monitoring with real-time feedback and context awareness. The physiological and motion data were detected by multisensors attached to the user and were processed in the PDA. Based on the quantitative physiological symptoms and behavioral response, the PDA provided warning feedback through sound or vibration. Wearable sensor technology is still in its early design stage and has not been applied in clinics.

### ***Telerehabilitation***

Telerehabilitation makes use of advanced technical developments in communication, including wireless vehicles and internet use, to deliver physical therapy to patients at home. Several studies presented in-home VR-based BF systems (177–180). At the user end, patients attached multiple sensors, accessed the BF training programs on the server via a telemedicine network, and received the training with visual or audible feedbacks. Patients may also wear other assistive device such as robots or neuroprostheses to aid the movement of impaired limb. At the other end, therapists could intervene, such as adjustment of task difficulty in the training program. The sensed data were quantified and stored in the database for later retrieving.

Current research that applies telerehabilitation in rehabilitation medicine focuses on investigation of the equivalence of assessment and therapy to in-personal assessment and therapy. The clinical application of telerehabilitation in the practice of physical therapy is very limited, however. One of the reasons is the affordability of assistive device for home use. Patients with sensorimotor deficits very likely do not possess the mobility to perform tasks alone; the assistive devices such as robots are essential for telerehabilitation. Nevertheless, most of therapeutic robots are for research or clinical setting; design of low cost, wearable assistive robots is highly demanded to promote telerehabilitation for rehabilitation (104). These demands may well transform into reality, as costs for health care rehabilitation

delivered to catastrophic injured patients are perceived to escalate. One obvious and potentially cost-effective vehicle to foster the rehabilitation process while channeling more of the treatment and management responsibilities onto caregivers is more extensive use of telerehabilitation.

### Future Research and Application on Task-Oriented Biofeedback

The message contained in this chapter should, by no means, imply abandonment of classic EMGBF. Rather, the more effective biofeedback training protocol may start from localized muscle or joint biofeedback retraining, followed by task-oriented training to enhance the motor function. In addition, although task-oriented biofeedback shows promise for functional motor recovery, strong evidence is still lacking. For example, the number of patients in many of the studies cited was small, and some reported that benefits from task-oriented biofeedback were not consistently observed among all participants. Clearly, more clinical RCTs are needed to quantify the efficacy of task-oriented biofeedback therapy.

Our efforts to introduce engineering designs are driven by a need to promote the awareness of existing rehabilitation technologies. Recent advances in technologies are encouraging; however, these technologies are immature, and their clinical value is unclear. In the future, therapists and clinical researchers are urged to study carefully those factors contributing to motor deficits in different patient population; establish clear training goals; assign necessary biofeedback indices in task-oriented biofeedback training; and work closely with rehabilitation engineers to assist the clinical evaluation of these new techniques.

### SUMMARY AND CONCLUSION

Biofeedback remains an important adjunct to the tools of the rehabilitation therapies; it has been subjected to intensive scientific scrutiny with controlled studies of varying quality pervading its history, and ineffective procedures are being extricated. In addition to traditional, static BF training strategy, further BF study may shift attention from static to task-oriented biofeedback training, which may enhance motor functional recovery. Moreover, novel rehabilitation technologies such as VR, therapeutic robots, and telerehabilitation are exciting and have been introduced independently or combined with BF applications. Collectively, the totality of advances among these technologies may bring BF-based rehabilitation into a new era.

### ACKNOWLEDGMENT

This chapter is dedicated to the late John V. Basmajian, M.D., often referred to as the “Father of EMG biofeedback” who mentored many rehabilitation scientists and clinicians and who authored preceding versions of this chapter.

# Therapeutic Electrical Stimulation in Neurorehabilitation

## INTRODUCTION

The clinical application of electrical stimulation (ES) to treat neurologic disease may be broadly classified as therapeutic or functional. The purpose of therapeutic ES is to improve the health or voluntary function by inducing physiological changes that remain after the stimulation is used. Therapeutic application of ES may either decrease impairment or prevent further impairment associated with immobility or disuse of a limb or organ system. The use of ES for functional purposes is distinct from therapeutic ES in that the benefits persist only during the period of intervention. The term functional electrical stimulation (FES) refers to application of electrical current to activate paralyzed muscles in precise sequence and intensity as to supplement or replace lost function. In FES applications, stimulation must be “on” to achieve a desired function; therefore, FES systems are usually designed to be worn by the user and are called neuroprostheses because they substitute for lost function. As an intervention in neurorehabilitation, specific applications of FES may have both neuroprosthetic and therapeutic benefit. This chapter is limited to the therapeutic applications of ES to treat the neurologically based disorders most commonly encountered in the clinical practice of Physical Medicine and Rehabilitation. Neuroprosthetic or FES applications of ES is reviewed in the chapter entitled Functional Neuromuscular Electrical Stimulation.

## HISTORY

The history of therapeutic ES dates back to 3,000 BC; archeological evidence suggests that Egyptians knew of the powerful electrical shock emitted by an electric catfish found in the Nile River. In ancient Egyptian tombs, hieroglyphics have been discovered which depict the *Malapterurus Electricus* (1), a species of catfish now known to possess electric organs innervated by a pair of electromotoneurons located within the cervical spinal cord. In 43 AD, Scribonius Largus, a physician to the Roman emperor Claudius, provided the first written documentation of the therapeutic application of ES (2). In the book entitled, “Compositions Medicamentorum,” he detailed the use of the electric torpedo fish for the transient relief of pain associated with headaches and gout. The torpedo fish, which could

produce electric shocks between 100 and 150 V, was applied either directly on the patient or placed in a pool of water in which the patient stood to provide therapeutic benefit.

It was not until the middle of the 18th century that potential medical applications of electricity became a focus of study. The Leyden jar, invented in 1745 by Pieter van Musschenbroek (1700 to 1748), was an early device for the storage of electricity which helped early researchers to try various therapeutic applications of electricity. In the 1750s, Benjamin Franklin noted the amnestic effect of electricity applied to the brain (3) and experimented with ES in an attempt to restore motor movement in stroke survivors (4). Luigi Galvani’s description of his “animal electricity” experiments in 1786 and the invention of the voltaic cell by Alessandro Volta (1745 to 1827) significantly contributed to the foundation for modern electrophysiology. Michael Faraday (1791 to 1867) in 1831 performed a series of experiments, establishing the concept of electromagnetic induction. His characterization of the relationship between a DC electric current and a magnetic field further laid a foundation for the therapeutic use of electricity. Duchenne De Boulogne (5) (1806 to 1875) in the mid-1800s used ES both as a therapeutic agent as well as a diagnostic agent to map functional anatomy. Despite these advances, medical skepticism of the therapeutic value of ES persisted through the end of the 19th century.

The advent of the 20th century heralded significant advances in the therapeutic applications of ES. ES of the human sensory cortex was first reported by famed neurosurgeon Harvey Cushing (1869 to 1939) in 1909 (6). Walter Rudolph Hess (1881 to 1973) reported “affective responses” to hypothalamic stimulation in 1928 (7). In 1969, D.V. Reynolds described the analgesic effect of ES on the periaqueductal gray matter of the brain in an animal model (8). Today, transcutaneous electrical nerve stimulation (TENS) and neuromuscular electrical stimulation (NMES) systems are commercially available and routinely employed for the treatment of neuropathic pain and paralysis. Spinal cord stimulation (SCS) and deep brain stimulation (DBS) have been shown to be safe and efficacious for the treatment of various neurological symptoms including neuropathic pain and movement disorders. The burgeoning field of Neuromodulation encompasses the reversible therapeutic modulation of central, peripheral, and autonomic nervous system activity via ES and proposes to provide

practical, clinical treatment options for neurologically disabled patients in the 21st century.

## TENS FOR PAIN

TENS is a widely used form of electroanalgesia based on the “gate control theory of pain” postulated by Melzack and Wall in 1965 (9). The “gate theory” of pain control states that stimulation of large somatosensory fibers in peripheral nerves or at the dorsal column can effectively inhibit the central transmission of nociceptive signals carried by small, unmyelinated C-fibers from the periphery. Activation of low-threshold myelinated fibers essentially “closes the gate” at the presynaptic level of the dorsal horn of the spinal cord to produce transient pain relief. In 1967, Wall and Sweet (10) demonstrated the electroanalgesic effect of transcutaneous sensory stimulation applied at 100 Hz to patients with chronic cutaneous pain.

The proposed mechanism of neuromodulation via TENS remains controversial. The literature supports a primary effect via presynaptic inhibition at the level of the dorsal horn of the spinal cord as evidenced by changes in neurotransmitter levels associated with application of TENS. In an animal model, high-frequency TENS has been shown to activate delta-opioid receptors and thus reduce the release of glutamate and aspartate at the level of the spinal cord which would otherwise be elevated in association with joint inflammation (11). TENS has also been shown to reduce production of substance P in the dorsal root ganglion and thus suppress nociception via C-fibers in the peripheral nerve (12). Central mechanisms have been proposed to explain the effect of TENS including a neuromodulating effect via descending supraspinal sites such as the rostral ventromedial medulla (13). In a study examining the effect of sensory input on corticospinal excitability, short-term high-frequency TENS was found to decrease human motor cortex excitability (14). Lastly, research has suggested that TENS-mediated hypoalgesia may, in part, be the result of a direct peripheral effect (15).

The first modern TENS unit (16) received a U.S. patent in 1974. A TENS unit is a battery-powered electronic pulse generator that provides low-voltage electrical current through transcutaneous electrodes. A constant voltage stimulator allows for fluctuations in current intensities that may occur with variable impedance of the electrodes, skin, and tissues. A TENS unit is programmable and optimal settings are determined based on the symptomatic response of the individual patient. The parameters for prescription of TENS include stimulation intensity (mA), pulse frequency (range 2 to 250 Hz), and pulse duration (50 to 1,000  $\mu$ s). Conventional TENS is the most commonly applied mode of stimulation for rapid-onset, localized anesthesia. Conventional TENS is characterized by high stimulation frequency (>100 Hz), low intensity (10 to 30 mA), and short pulse duration (50 to 100  $\mu$ s). Acupuncture-TENS is characterized by high intensity stimulation (sufficient to evoke muscle contraction) delivered at low frequency (<4 Hz) and longer pulse duration (>200  $\mu$ s). While acupuncture-TENS

may produce a more sustained analgesia, tolerance is less than with conventional TENS. Lastly, pulsed (burst) TENS is essentially a combination of conventional and acupuncture-TENS, and is characterized by bursts of high frequency stimulation (>100 Hz) delivered in bursts at lower frequency (<4 Hz).

No specific advantage is established for pulsed TENS as compared to conventional TENS. The clinician determines the placement of transcutaneous electrodes based on the pain location and may be influenced by trigger points, cutaneous nerve paths, and location of traditional acupuncture sites. For low back pain, for example, transcutaneous electrodes may be placed several centimeters apart either on or adjacent to the painful region, with stimulation being delivered with a pulse frequency of 80 Hz, pulse duration of 100  $\mu$ s, and amplitude set to the submotor threshold, which varies widely from patient to patient. The onset of analgesia is immediate and may persist beyond the interval of time that the TENS unit is stimulating.

Indications for the use of TENS include both neurogenic pain (deafferentation pain, phantom pain, sympathetically mediated pain, postherpetic neuralgia, trigeminal neuralgia, atypical facial pain, brachial plexus avulsion) and musculoskeletal pain (joint pain associated with rheumatoid arthritis, osteoarthritis, acute posttraumatic pain). Placement of TENS electrodes is contraindicated on or near the eyes, in the mouth, transcranially, over the carotid sinuses (vasovagal reflex), anterior neck (laryngospasm), on areas of decreased or absent sensation, or over the trigeminal nerve (if history of herpes zoster induced trigeminal neuralgia). TENS should not be used in epilepsy or pregnancy, or in patients with an implanted cardiac pacemaker or defibrillator due to risk of interference or failure. Skin irritation and electrical burn are the most commonly reported complications, but in general, TENS is well-tolerated.

Despite widespread usage and a 40-year history as an adjunctive treatment to pharmacologic pain management, the therapeutic efficacy of TENS remains controversial. A recent Cochrane review (17) analyzed 25 randomized clinical trials (RCTs) (128 subjects) to determine the efficacy of TENS for chronic pain. Trials were included that compared high-frequency TENS with (a) sham TENS (control), (b) no treatment (control), and (c) low-frequency TENS. In 13 of 22 controlled studies, there was a positive analgesic outcome in favor of TENS. No difference in analgesic efficacy was found in seven of nine studies which compared high- and low-frequency TENS. A second Cochrane review (18) analyzed four RCTs ( $n=585$  subjects) to determine the efficacy of TENS as compared to placebo for the specific treatment of chronic low back pain. A qualitative synthesis was completed as clinical heterogeneity prevented the use of meta-analysis. The authors noted that there was conflicting evidence about whether TENS was beneficial in reducing back pain intensity and back-specific functional status. They concluded that the evidence from the small number of placebo-controlled trials did not support the use of TENS in the routine management of chronic LBP. In summary, TENS is a noninvasive, widely used modality for

pain that is easy to apply with relatively few contraindications. However, high quality, randomized, controlled clinical trials remain necessary to definitively assess the therapeutic role of TENS in the management of pain.

## NMES FOR MOTOR RELEARNING

Motor relearning is defined as the reacquisition of motor skills following central nervous system injury. Research on central motor neuroplasticity supports a primary role of goal-oriented, active repetitive movement training to enhance motor relearning. Asanuma and Keller demonstrated that ES of the somatosensory cortex alone or in conjunction with thalamic stimulation in an animal model induces long-term potentiations (LTP) in the motor cortex (19). They hypothesized that proprioceptive and cutaneous afferent impulses associated with repetitive movements induce LTP in the motor cortex, which then modify the excitability of specific motor neurons and facilitate motor relearning (20). Consistent with this hypothesis, nonhuman primate research has demonstrated that after local damage to the motor cortex, goal-oriented, active repetitive movement training of the paretic limb shapes subsequent functional reorganization in the adjacent intact cortex, and that the undamaged motor cortex plays an important role in motor relearning (21). Repetitive movements that require the development and practice of new motor skills are the kinds of behavioral experiences that induce long-term plasticity in motor maps (21). When animals are trained to perform new tasks such as retrieving food pellets from a small well (22–24) or a rotating well (25), there is evidence of task-specific cortical reorganization. However, repetitive movement tasks that do not require skill acquisition (i.e., motor tasks that are already mastered and, therefore, are easy to carry out and require minimal or no cognitive effort) are not associated with any significant changes in the motor cortex (24,25).

The use of NMES-mediated goal-oriented repetitive movement therapy for motor relearning is predicated on repetitive movement therapy research. Acute administration of ES to a peripheral nerve activates both sensory and motor structures in the brain (26,27) and reduces the intracortical inhibition (28,29). Functional MRI (fMRI) studies show cortical responses to NMES-facilitated movement in both the upper (30) and lower (31) extremities, which suggests that repetitive movement therapy mediated by NMES has the potential to facilitate motor relearning via cortical mechanisms.

NMES may also facilitate motor relearning via spinal mechanisms. Rushton theorized that the corticospinal-anterior horn cell synapse is a Hebb-type, modifiable synapse and that it can be modified by NMES (32). Originally proposed in 1949, “Hebb’s rule” (33) states: “When an axon of cell A... excite(s) cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells so that A’s efficiency as one of the cells firing B is increased.” The synapse is thought to be strengthened by the coincidence of presynaptic and postsynaptic activities.

Under normal circumstances, neural activity in the pyramidal tract easily discharges the anterior horn cells and the strength of the presumed Hebb-type pyramidal tract/anterior horn cell synapse is maintained by this traffic. However, following brain injury, neural activity in the pyramidal tract is significantly reduced. Failure to restore this traffic leads to “decorrelation” of presynaptic and postsynaptic activities, which weakens the synapse. Rushton suggested that NMES-mediated antidromic impulses provide an artificial means to synchronize presynaptic and postsynaptic activity in the affected population of anterior horn cells. Accordingly, he predicted that combining NMES with simultaneous voluntary effort is an effective means of facilitating motor relearning.

Regardless of cortical or spinal mechanisms, experimental and theoretical considerations suggest that the necessary prerequisites for NMES-mediated motor relearning include repetition, novelty of activity, concurrent volitional effort, and high functional content.

## Types of NMES for Motor Relearning

Three NMES paradigms have been used for motor relearning: cyclic NMES, EMG-mediated NMES, and as a neuroprosthesis. Cyclic NMES provides repetitive activation of muscles without input from the stroke survivors. The activity is novel in that the stroke survivor has difficulty performing the task without the NMES; however, the task is not functionally relevant. EMG-mediated NMES couples cognitive intent and NMES-mediated muscle contraction. This approach may be applied to patients who can partially activate a paretic muscle but are unable to generate sufficient muscle contraction for adequate exercise or functional purposes. The approach incorporates novel tasks and includes cognitive investment, but the task is not functionally relevant. Neuroprostheses provide repetitive movements in the context of functional tasks that are novel; thus, neuroprostheses have a theoretical advantage over both cyclic and EMG-mediated NMES for motor relearning.

## Upper Limb Applications

RCTs have investigated the efficacy of cyclic NMES in enhancing upper-limb motor relearning (34–38). Transcutaneous electrodes are typically placed over the motor points of the finger and wrist extensors. Four studies reported improved outcomes in motor impairment at the end of treatment, with mild to moderately impaired subjects benefiting most. Two acute stroke studies reported sustained effect (36,37) and two studies reported improvements of activity limitation at the end of treatment (37,38).

EMG biofeedback, position, or EMG-triggered NMES have been evaluated for upper limb motor relearning in six controlled trials (39–44). All six studies demonstrated improved outcomes in motor impairment at the end of treatment; one study showed a sustained effect at 9 months post-treatment (40). Two studies demonstrated decreased activity limitation (41,44). Finally, three studies reported evidence of central mechanisms using neurophysiologic assays including reaction time and fMRI (42–44).

**FIGURE 71-1.** Contralaterally controlled functional electrical stimulation (CCFES) system in hemiparesis. Stimulation of the impaired left upper extremity is controlled via sensor glove worn on right upper extremity. (Courtesy: Jayme S. Knutson, PhD, Cleveland FES Center.)

The initial review of these studies suggested that NMES is efficacious in reducing motor impairment but not activities limitation (45). The authors suggested that the effect is more significant for those with milder impairments. A subsequent review by the same group concluded that EMG-mediated NMES may be more effective than cyclic NMES (46).

However, a more recent meta-analysis concluded that EMG-mediated NMES was no more efficacious than “usual care” in facilitating motor relearning (47). They noted that most studies were with chronic stroke survivors and results might be different among acute stroke survivors. Consistent with this conclusion, two small RCTs failed to demonstrate the superiority of EMG-mediated NMES over cyclic NMES (48), or usual care (49) among chronic stroke survivors. While acute studies are ongoing, at present it remains uncertain whether cyclic and EMG-mediated NMES are efficacious in facilitating upper limb motor relearning among chronic stroke survivors.

There is emerging evidence that hand neuroprostheses may facilitate motor relearning in the poststroke patient population. Two recent RCTs using a hybrid brace-NMES device that incorporates surface electrodes into a brace for hand grasp and release showed significant improvements in motor impairment (50,51). A third RCT of multichannel NMES also resulted in significant improvement in upper limb motor function (52). Several novel neuroprosthesis approaches with encouraging preliminary results are presently under investigation, including injectable microstimulators (53), contralaterally controlled surface FES (Fig. 71-1) (54), and the incorporation of work stations (55). Additional studies are needed to confirm

the motor relearning effect of hand neuroprostheses, especially with respect to translation to functional abilities.

### Lower Limb Applications

Studies of stroke patients treated with cyclic lower limb NMES have demonstrated enhanced walking ability, increased maximal isometric contraction of the ankle dorsiflexors and plantarflexors, increased dorsiflexion torque, increased agonist EMG activity, and decreased EMG co-contraction ratios (56–58). In one controlled RCT, acute stroke survivors treated with lower extremity NMES and on standard rehabilitation for 3 weeks were more likely to return to a home setting at discharge from rehabilitation compared to controls who did not receive the NMES (58).

The potential motor relearning effect of lower limb neuroprostheses has been evaluated. After using a single channel peroneal nerve stimulator (PNS), Lieberman et al. commented, “On several occasions we observed, after training with the electrophysiologic brace...patients acquire the ability of dorsiflexing the foot by themselves” (59). Since then, case studies using either implanted or transcutaneous electrodes have described similar post-FES observations of improved ambulatory function, more normal EMG muscle activation patterns, emergence of EMG signals in previously silent muscles, increased strength of EMG activity, and decreased co-contraction of antagonist muscles (60–66). A recent meta-analysis of the effect of nonimplanted FES devices on gait speed concluded that FES was effective in improving poststroke gait speed (67). However, studies with implantable PNSs have yielded conflicting results (68,69).

Since gait deviation is not limited to ankle dysfunction, multichannel transcutaneous stimulation systems have been investigated in hemiplegia (70–72). However, the therapeutic application of transcutaneous systems becomes more difficult due to limited muscle selectivity, poor reliability of stimulation, and pain of sensory stimulation. Therefore, percutaneous stimulation systems, which use fine wire electrodes, have been explored for lower-limb motor relearning (73–75). In a single-blinded RCT, chronic stroke survivors receiving gait training with percutaneous NMES demonstrated significant improvements in gait components as measured by the Tinetti Gait scale and knee flexion coordination relative to controls who did not receive NMES (76).

### Summary and Future Directions

Repetitive movement therapy, mediated by NMES, has the potential to facilitate motor relearning via both cortical and spinal mechanisms. The necessary prerequisites for NMES-mediated motor relearning include repetition, novelty of activity, concurrent volitional effort, and high functional content. Although earlier studies suggested that cyclic and EMG-mediated NMES reduces motor impairment, more recent data, especially among chronic stroke survivors, raise doubts regarding their therapeutic benefits. These approaches may be efficacious among acute stroke survivors, but there are insufficient data to confirm this. While the efficacy of cyclic

and EMG-mediated NMES in facilitating motor relearning remains uncertain, the implementation of neuroprostheses will likely have significant clinical impact due to the higher functional content.

## SPASTICITY

For over a century, researchers have attempted to quantitate the effect of ES on spasticity. Duchenne (5), in 1871, noted that stimulating the muscle antagonist to a spastic muscle resulted in a relaxation of the spastic muscle. In 1952, Levine et al. (77,78) published two articles on the inhibitory effect of ES on the spasticity of the antagonist muscles. More recently, Dewald et al. (79) has studied the effects of 10 minutes of low-intensity skin stimulation applied over the spastic biceps muscle of stroke survivors. In seven of nine subjects, ES resulted in both a reduction in peak reflex torque responses in elbow flexors and extensors that lasted for 3 minutes and a significant increase in mean threshold angle for the onset of reflex torque such that a greater angular torque was required to initiate the stretch reflex response. The authors suggested that the changes in reflex torque may reflect synaptic plasticity of spinal circuitry outside the stretch reflex loop.

The effects of TENS on spasticity in patients with various upper motor neuron (UMN) dysfunction have been described. TENS in spastic hemiparesis is associated with an increase in soleus H reflex latencies (80,81) and F-wave latencies (81), decrease in *H/M* and *F/M* ratios (81), and decrease in EMG co-contraction ratios (57). Clinical evidence of spasticity reduction associated with TENS applications in stroke include decrease in Modified Ashworth Scores (82), magnitude of plantar flexion stretch reflex (57), and resistive ankle torques (83). Underlying mechanisms for spasticity reduction secondary to TENS have been proposed and include both an enhancement in presynaptic inhibition of the spastic plantarflexor and a “disinhibition” of descending voluntary commands to the paretic dorsiflexor motor neurons (57). A sustained therapeutic effect of TENS on spasticity has not been demonstrated (35).

The effect of TENS on spasticity may be related to stimulation parameters. In a study of 32 patients with spasticity of spinal origin, high frequency (100 Hz) but not low frequency (2 Hz) stimulation was effective for the short-term amelioration of spasticity (84). The antispastic effect induced by high-frequency ES was partially reversed by a high dose of naloxone, indicating that the effect may be mediated in part by endogenous opioids.

Clinical evidence of a therapeutic modulation of spasticity associated with NMES is equivocal. Early case series suggested short-term benefits of NMES on spasticity in hemiparesis (85) and spinal cord injury (SCI) (86,87). Stimulation of the tibialis anterior (TA) muscle, prior to a mechanical stretch of the soleus muscle, has been shown to inhibit the stretch reflex of the soleus (88). In a study of spastic hemiparesis, subjects treated for 1 month with lower extremity ES showed a trend toward reduced spasticity based on  $F_{\max}/M_{\max}$  ratio, H-reflex

latencies, and H-reflex recovery curves (89). As compared to a Bobath inhibitory program, a program of NMES of the dorsiflexor muscles resulted in an increase in passive ankle range of motion and reduction in modified Ashworth score (90). Other researchers have suggested that interaction of electrocutaneous stimulation with an impaired human motor control system may result in unstable reflex loops and cause excessive spastic reactions. In a study of SCI, onset times of spastic activity during an electrically elicited dorsiflexion contraction were noted to shorten with increased stimulation frequency though a stimulation burst did have a spasticity reduction effect on a subsequent burst, suggesting a potential short-term therapeutic effect of stimulation (91).

A therapeutic effect of upper (92) and lower extremity neuroprostheses on spasticity has been suggested. Several studies (93–95) have demonstrated that a neuroprosthesis can effectively open a spastic hemiparetic hand; however, adjustments of stimulation intensities and conditions of upper extremity positioning were necessary for maximal functional response. Short- (96) and longer-term (97) applications of PNS-assisted ambulation have been associated with a decrease in amplitude of the Achilles tendon reflex (96), and a decrease in the tonic activity of the TA and triceps surae muscles (97).

The efficacy of adjuvant ES combined with botulinum toxin A for treatment of spasticity has been proposed (98–101), based on animal studies demonstrating enhanced toxin uptake and accelerated onset of paralytic effect by ES. Frasson et al. (99) reported that low-frequency ES (4 Hz), but not high frequency ES (25 Hz) accelerates the effect of botulinum toxin on neuromuscular blockade. In two small controlled studies, Botulinum toxin combined with NMES reduced spasticity in both the upper (102) and lower (103) extremities. However, a recent single-blinded study found no difference in efficacy of low-dose Botulinum toxin (100 U) plus short-term ES versus high-dose Botulinum toxin (400 U) to treat equinovarus spasticity (104).

In summary, there is evidence of short-term electrophysiologic effects of TENS on spasticity in patients with various UMN disorders. The functional relevance of short-term decreases in spasticity secondary to TENS is unclear; long-term modulation of spasticity secondary to TENS has not been established. A therapeutic effect of NMES on spasticity has not been established; variable outcomes may be influenced by stimulation parameters, application methods, quantification measures, and etiology of UMN dysfunction. There is evidence that NMES may enhance the antispasticity effect of Botulinum toxin; however, the superiority of NMES to other adjuvant interventions has not been established.

## BONE DENSITY

The physiologic alterations of bone associated with immobility in the neurologically impaired patient are well-described. Following SCI, weight-bearing trabecular-rich sites such as the distal femur and proximal tibia show the greatest amount of

demineralization. Pathologic fractures following minor trauma can be caused by reduced bone mass in association with modified bone matrix composition (105,106). Capacitively coupled electrical fields have been shown to prevent and reverse osteoporosis in animal studies (107–111). Various applications of ES have been shown to stimulate osteogenesis (112), positively affect bone mineral density (BMD) (113,114), and enhance fracture healing (115) in animal models.

Studies have described variable short-term effects of NMES (116) and FES-cycling (117–121) programs on bone density in SCI. However, several studies have found site-specific effects of FES-cycling on neurogenic osteopenia. In a controlled study (122), 6 months of FES-cycling resulted in a partial reversal of BMD loss in the distal femur and proximal tibia in SCI; however, the effect was not sustained 6 months after completion of the FES-cycling program. Belanger et al. (123) measured the BMD of the distal femur, proximal tibia, and mid-tibia in SCI following a 6-month FES-cycling program. At baseline, the BMD of SCI subjects was lower than that of controls. After training, the distal femur and proximal tibia had recovered approximately 30% of the bone loss. Shields and Dudley-Javoroski (124) applied unilateral NMES to the plantar-flexor muscles in SCI using each subject as his own control. A 2-year training program resulted in a 31% higher distal tibia trabecular BMD in trained limbs as compared to untrained limbs (Fig. 71-2).

In summary, the literature supports the use of ES, in the form of lower extremity FES-cycling, to enhance bone mineral density at the distal femur and proximal tibia in SCI. However, the therapeutic effects on BMD are short-term and have not been shown to persist beyond the period of the FES-cycling intervention. The clinical efficacy of ES to prevent osteopenia, enhance BMD, or prevent fractures in non-SCI UMN paralysis has not been established.

**FIGURE 71-2.** Mean  $\pm$  SE bone mineral density at the distal tibia (4% site) for four subjects who underwent pQCT analysis. (Shields RK, et al. *J Neurophysiol.* 2006;95:2380–2390. Copyright 2006 The American Physiological Society.)

## FATIGUE, MUSCLE ATROPHY, AND STRENGTHENING

NMES has been demonstrated to have therapeutic benefit for muscle weakness and atrophy following central nervous system injury. Loss of muscle mass may occur as a result of spinal motoneuron injury resulting in denervation atrophy or central pathway injury resulting in disuse atrophy. Muscle fiber alterations at the cellular level form the basis of present understanding of NMES-associated muscle strength enhancement. Skeletal muscle contains type I (slow-twitch) fibers and type II (fast-twitch) fibers. Type I fibers are fatigue-resistant with high oxidative capacity. Type II fibers have high glycolytic capacity with the ability to metabolize adenosine triphosphate (ATP) more quickly and are thus associated with short, forceful contractions. NMES reverses the transformation of type I fibers to type II fibers, commonly seen following an UMN injury (125). In an animal model (126), changes in fiber population and myosin light chain patterns, at the level of the mitochondria and sarcoplasmic reticulum, are associated with intermittent or continuous stimulation. Ljubicic et al. (127) noted numerous biochemical and physiological adaptations induced by chronic low-frequency ES in an animal model including: alterations of calcium dynamics and myofibrillar proteins, changes in mitochondrial enzymes, myoglobin, and induction of angiogenesis. Training-induced changes in fatigue resistance seem to arise, in part, from an improved oxidative capacity. In a controlled study that compared selected morphological and metabolic properties of single fibers from the TA (128) SCI subjects who received 6 months of ES increased both the proportion of type I fibers and activity of succinate dehydrogenase (SDH) in both fiber types. Muscle fatigue has also been correlated to the level of SDH activity (129). In a study of quadriceps fiber characteristics in SCI, 12-weeks of low-frequency ES increased the SDH activity by 76% though fiber diameter and myosin heavy chain (MHC) expression remained unchanged. The specific effects of NMES-facilitated exercise on the motor unit including muscle fiber transformation as an adaptive response have been summarized (130,131).

NMES can play a role in preventing or reversing muscular atrophy following UMN injury. Long-term FES training programs post-SCI can prevent lower extremity muscle atrophy (132), increase cross-sectional muscle area (133,134), and preserve the physiological properties of specific muscles (peak torque, fatigue index, torque-time integral, and contractile speed) (124). In a study by Kern (135), an increase in quadriceps muscle fiber diameter (mean 59%) and muscle cross-sectional area (mean 30%) was noted following an 8-month training period with FES paraplegic subjects. Dupont Salter et al. (136) investigated the effects of four different stimulation paradigms on disuse atrophy produced in the TA, lateral gastrocnemius, and soleus muscles of paralyzed rats. Lower frequency stimulation (2 Hz) applied to the soleus resulted in 10% mean atrophy as compared to 26% atrophy at 10 Hz and 32% atrophy in unstimulated, paralyzed controls. The authors proposed possible mechanisms for the selective effect

of low-frequency ES on muscle atrophy including variable muscle loading conditions, effects of both animal gender and anesthesia on hormone levels (cortisol, testosterone, growth hormone), and conversion of fast to slow muscle fibers associated with higher-frequency stimulation-induced increases in basal cytosolic calcium levels.

A limited number of studies have evaluated the efficacy of NMES on muscle strength when applied to the upper extremity. Peckham et al. (137) demonstrated an increase in contractile force resulting in functional gain with the application of ES to the forearm finger flexors of ten quadriplegic patients. However, Seeger et al. (138) studied the effect of FES-assisted exercise versus isotonic exercises and found no increase in maximum voluntary upper extremity force in SCI. In separate studies, NMES applied to the wrist extensors in hemiplegia has also been demonstrated to be associated with higher isometric wrist extension torques (37), greater isometric finger extension (44), and improved grip speed (139).

The ability of NMES, used in various applications, to enhance the strength of specific lower extremity muscles post-SCI has been demonstrated. Cyclic NMES to the quadriceps has been shown to enhance quadriceps muscle strength (123,140). Lima (141) compared NMES to isotonic exercises of the knee and found that flexor torque, though not extensor torque, was increased in the NMES group. Similarly, FES-cycling programs (142,143) and lower-extremity FES-exercise programs (144) have been shown to be effective in increasing the muscle strength in SCI. Sloan et al. (145) reported improvements in voluntary isometric strength, stimulated isometric strength and stimulated isometric endurance of the quadriceps, muscle grading of the quadriceps and biceps femoris and the cross-sectional areas of the quadriceps and total thigh muscle associated with a 3-month FES-cycling program in SCI. Guidelines for FES training in SCI were proposed by Petrofsky et al. (146) who studied 90 paraplegic patients and determined that the optimal protocol for FES-isokinetic exercise of the quadriceps was a three time per week regimen for 30 min/day with equal alternating periods of work and rest. Kern et al. (147) determined that the striated appearance of normal skeletal fibers may be maintained up to 20 years post-SCI and thus proposed that there was no upper limit for the initiation of a training program based on FES in SCI. Several reviews outline the use of NMES to increase strength and endurance in the SCI (148–150), stroke (151), and able-bodied patient (152) populations.

In summary, on a cellular level, NMES has the ability to reverse the transformation of type I fibers to type II fibers that is commonly seen following an UMN injury. NMES can play a preventative role in minimizing the amount of muscular atrophy seen following an UMN injury. The ability of cyclic NMES or FES-cycling to reverse muscle atrophy and enhance lower extremity muscle strength in SCI is supported by the literature and accepted in clinical SCI care. While NMES may be clinically used to prevent muscle atrophy and enhance strength in other UMN disorders including stroke, the clinical and functional relevance of resultant strength changes has not been established.

## TISSUE OXYGENATION AND WOUND HEALING

Early studies (153,154) proposed the therapeutic benefit of ES in the treatment of soft tissue injury and wound healing. Subsequent studies have demonstrated that ES affects wound healing by both a direct local tissue effect at the cellular level and via an enhancement of angiogenesis, tissue perfusion, and oxygenation (155–157). Certain chemotactic factors found in wound substrates contribute to tissue repair processes by attracting cells, which carry positive or negative charges, into the wound environment. ES can facilitate the induction of directional cell migration (i.e., electrotaxis) (158) of neutrophils, macrophages, epidermal cells, and fibroblasts into the wound. These cells accelerate wound healing through their specific cellular roles in autolysis, cellular protein synthesis, mitotic cell division, and anti-inflammatory activities (159,160). In a recent review, Kloth (155) presented the relationship between endogenous bioelectric currents and wound repair, and reviewed clinical research applications of ES on wound healing.

ES induces angiogenesis to enhance tissue perfusion and oxygenation. In a study by Zhao et al. (161), applied electric fields of small physiological magnitude directly stimulated vascular endothelial growth factor (VEGF) production by endothelial cells *in vitro*. They proposed that endogenous electric fields (EFs) might play a role in angiogenesis *in vivo* by stimulating the VEGF receptor signaling pathway to induce key preangiogenic responses. Other animal studies have demonstrated ES-induced changes including increased capillary-to-fiber ratios, blood perfusion, transformation of muscle fiber types from mixed (oxidative and glycolytic) to primarily oxidative fibers, and improved muscle fatigue (162–166).

*In vivo* studies support the efficacy of ES for wound healing. In a controlled study, patients with stage IV decubitus ulcers treated with high voltage ES healed at a mean rate of 44.8% per week with 100% closure in a mean of 7.3 weeks whereas ulcer size of the control group increased over the same period of time (167). In a study of 30 patients with sacral or leg ulcers, low-intensity DC significantly accelerated the rate of wound healing in humans 1.5 to 2.5 times faster when compared to conventional wound therapy (168). In a meta-analysis, Gardner et al. (157) analyzed 15 studies, which included 24 ES samples and 15 control samples. The rate of healing per week was 22% for ES and 9% for controls; the net effect of ES was 13% per week, an increase of 144% over the control rate. Factors which appear to be predictive of wound healing by ES include wound size, patient's age, time elapsed from wound appearance to the beginning of the treatment, width-to-length ratio, location, and type of treatment (169). Additionally, biphasic- and direct-current stimulation may result in faster healing of chronic wounds (169).

An optimal delivery system for wound healing and pressure sore prevention in patients who lack sensation or are unable to perform independent pressure relief has not been established. Electrode design and ES delivery systems must consider both

temperature (170) and nonhomogeneity of the wound (171) that can affect current delivery and skin responsiveness. In an able-bodied adult, intermittent ES has been shown to increase oxygenation level of the buttock muscles by 6% (172). The role of percutaneous ES (173) and an implanted NMES stimulation system (174,175) consisting of intramuscular electrodes with percutaneous leads has been proposed. In a series of SCI patients, Bogie and Triolo (175) found that 8 weeks use of an implantable NMES device was associated with an increase in the unloaded tissue oxygen level and a reduction in the ischial region pressure. A second study (174) demonstrated an increase in gluteal muscle thickness of 50%, decrease in regional interface pressures of 20%, and an increase in tissue oxygen levels associated with the implanted system.

In summary, ES has a therapeutic effect on wound healing by facilitating the induction of cell migration (neutrophils, macrophages, epidermal cells, and fibroblasts) into the wound and via angiogenesis, tissue perfusion, and oxygenation. The therapeutic efficacy of ES on wound healing is dependent on wound characteristics and ES parameters and delivery systems. Research suggests that biphasic- and direct-current stimulation applications result in faster wound healing rates. Further research is needed to determine the clinical efficacy and viability of implanted NMES systems for pressure wound healing and prevention.

## CARDIOVASCULAR AND PERIPHERAL HEMODYNAMIC EFFECTS

NMES can affect specific cardiovascular and peripheral hemodynamic parameters when applied therapeutically to subjects with muscle paralysis. The specific effect of NMES on peripheral arterial blood flow, arterial diameters, and pressures has been variable. In a study of able-bodied adults, a linear increase in femoral arterial blood flow was associated with increasing frequencies of transcutaneous NMES applied to the leg muscles (176). Stoner et al. (177) evaluated the effects of NMES-induced quadriceps exercise therapy on posterior tibial artery resting diameter, flow-mediated dilatation, and arterial range in SCI subjects. Following 18-weeks of NMES training, flow-mediated dilatation and posterior tibial arterial range improved. Sherry et al. (178) studied the effects of low-frequency (2 Hz), burst-mode TENS applied over the common peroneal and tibial nerves in healthy controls. When TENS was applied at 25% above the motor threshold a transient increase in calf blood flow was detected; however, TENS had no effect on arterial pressure regardless of stimulation intensity. Similarly, Sabatier et al. (179) found no change in femoral artery diameter on resting, reactive hyperemic, and exercise blood flow associated with 8 weeks of NMES-facilitated quadriceps resistance training in SCI.

NMES-facilitated exercise may enhance venous return, stroke volume (SV), and cardiac output (CO) in SCI. NMES-facilitated knee exercise resulted in an increase in CO associated with an increase in venous return but no change in

heart rate (HR) (180). In a study of orthostatic responses in SCI, Raymond et al. (181) noted a 20% increase in SV, 16% increase in CO, and a 12% decrease in total peripheral resistance associated with NMES-induced muscle contractions. Lastly, an increase in blood flow and decrease in venous pooling was associated with a reduced rate pressure product in SCI subjects who performed arm crank ergometry while concomitantly receiving NMES-induced leg contractions (182).

Lower extremity FES-treadmill training with body weight support (BWS) has been studied for its therapeutic effect on cardiovascular responses in SCI (183,184). In a controlled study, Carvalho (184) noted significant increases in oxygen uptake, carbon dioxide production, pulmonary ventilation, and systolic blood pressure (SBP) following 6-month FES-treadmill training. In a study of the training effects of FES-assisted ambulation in SCI (185), effects consistent with central cardiovascular adaptations, including a posttraining increase in peak oxygen uptake, peak power output, and time to fatigue, were noted. Lastly, in a study of chronic tetraplegic subjects who underwent 3-month FES-treadmill gait training with BWS (186), resting and exercise SBP increased from baseline without change in HR.

FES-leg cycle ergometry (FES-LCE) programs have also been shown to improve the central cardiovascular fitness in the SCI patient population. In a series of studies (181,187–191), Raymond et al. examined the effects of FES-LCE on cardiovascular function. When arm cranking was combined with FES-LCE in paraplegia (188), a significantly higher oxygen uptake, SV, and expired ventilation volume was noted during submaximal, steady-state exercise, as compared to arm cranking alone. A subsequent study (189) demonstrated that CO was higher in paraplegic subjects, using FES-LCE as compared to voluntary leg cycling, at equivalent submaximal oxygen uptake rates. Faghri et al. (192) noted that HR and blood pressure significantly decreased during submaximal exercise, whereas SV and CO significantly increased, following a 12-week FES-LCE program. In a study which compared FES-LCE to a continuous passive motion program in six tetraplegic subjects, an increase in both CO and the arterial-venous oxygen difference accounted for an elevation of oxygen uptake (193). Lastly, Hooker et al. (194) suggested that peripheral circulatory adaptations develop in SCI patients during FES-LCE training. In a study of 18 SCI subjects, significantly higher peak oxygen levels (45%), oxygen uptake (23%), pulmonary ventilation (27%), HR (11%), CO (13%), and significantly lower total peripheral resistance (14%) were found following 16 weeks of FES-LCE.

In summary, various forms of NMES-facilitated lower extremity exercise training have been demonstrated to enhance venous return, SV, and CO in SCI. Beneficial training effects have been demonstrated with the application of NMES in the forms of NMES-facilitated exercise, NMES-assisted treadmill gait training, and FES-LCE. The therapeutic efficacy of NMES-facilitated exercise training programs to enhance cardiovascular and peripheral hemodynamic functioning has not been established for other UMN diagnoses.

## DEEP VENOUS THROMBOSIS PROPHYLAXIS

Factors contributing to the development of deep venous thrombosis (DVT) in the rehabilitation patient population include impaired venous return and hypercoagulability. Potential mechanisms for the therapeutic efficacy of ES for prevention of DVT have been proposed. In a study of 49 able-bodied subjects (195), ES resulted in a significant increase in venous femoral and popliteal blood flow in the calf and plantar muscles. In a study by Lindstrom et al. (196), intraoperative ES-induced tetanus of the calf muscles reduced calf venous volume approximately three times more efficiently than ES single impulses. No enhancement of the fibrinolytic activity of venous blood was observed in the postoperative period. A more recent study, however, suggests that ES may have an important antithrombotic effect on arterial and venous thrombosis. Aguejout et al. (197) explored the antithrombotic properties of ES using a laser beam-induced thrombosis animal model. Continuous ES was found to decrease the number of emboli and the duration of embolization both in arterioles and venules and reduce the amplitude and velocity of the ex-vivo platelet aggregation induced by ADP.

A therapeutic role of ES of the calf muscles for the prevention of venous thrombosis and embolism was first explored in 1949 (198). More recent studies that focused on the application of ES in the perioperative period to reduce the incidence of venous thrombosis have found variable degrees of efficacy (199–202). Merli et al. (203) compared the additive effects of ES in combination with low-dose heparin, heparin alone, and placebo in acute SCI. Only the combination of low-dose heparin and ES group had a significant reduction in the incidence of DVT. A second study by Merli et al. (204) reported that heparin, in combination with thrombo-embolism deterrent (TED) hose, was similarly effective to heparin plus ES. Two review articles (205,206) that focused on the incidence and prevention of DVT in acute SCI recommended the clinical use of ES in combination with low-dose heparin as a prophylactic measure based primarily on these two specific clinical trials.

In summary, sequential ES applied to the calf muscles appears to increase the venous blood flow. The ability of ES to prevent venous thrombosis in the perioperative period has not been established. ES, as an adjunct to low-dose heparin, may decrease the risk of venous thrombosis in acute SCI as compared to heparin alone. As an adjunctive therapy, however, ES provides no greater benefit than TED hose. No study has compared ES, as either a primary or adjunctive intervention, to low-molecular weight heparin (LMWH) which is presently a standard of care for prevention of venous thrombosis in the acute post-SCI period. Further studies are indicated to explore potential antithrombotic properties of ES.

## POSTSTROKE SHOULDER PAIN AND SUBLUXATION

Shoulder pain and subluxation are common complications following stroke. Poststroke shoulder dysfunction is characterized

by early spasticity and weakness which may progress over time to result in mechanical instability and diminished mobility at the glenohumeral joint. The relationship between poststroke shoulder subluxation and poststroke pain is complex. Shah et al. (207) found a 35% prevalence of rotator cuff, biceps or deltoid muscle tears and 53% prevalence of tendinopathy in chronic stroke patients with shoulder pain. Importantly, the presence of rotator cuff tears, rotator cuff and deltoid tendinopathies were not found to be related to the severity of poststroke shoulder pain. In a study of 107 acute stroke subjects (<30 days poststroke), glenohumeral subluxation was present in 48.6% of patients (208). Presently, transcutaneous and intramuscular NMES of the supraspinatus, trapezius, and deltoid muscles are potential treatment options under investigation to reduce subluxation, improve biomechanical integrity, and reduce pain.

Eighty-one percent of patients may develop subluxation following stroke (209). NMES applied to the shoulder has the ability to reduce poststroke shoulder subluxation. In a study that compared conventional physical therapy (PT) with and without NMES to the supraspinatus and posterior deltoid muscles (210), the NMES group showed significant improvement in arm function, EMG activity of the posterior deltoid, range of motion, and reduction in subluxation. Studies suggest that a therapeutic program of NMES applied to the shoulder may reduce subluxation in both acute (211) and chronic (212) poststroke patients. However, in a controlled study, Wang et al. (213) focused on duration of poststroke and compared the effectiveness of 6 weeks of NMES applied 6 h/day to the supraspinatus and posterior deltoid muscles in the acute (<1 year) versus chronic (>1 year) poststroke periods. Shoulder NMES was only effective in reducing subluxation in the acute stroke group. A meta-analysis (209) determined that transcutaneous ES applied to the shoulder and combined with conventional therapy, prevented on an average 6.5 mm of shoulder subluxation as compared to 1.9 mm with conventional therapy alone. The authors concluded that NMES reduced or prevented shoulder subluxation and improved motor impairment in the acute poststroke period, but not in the chronic poststroke period. Lastly, Wang (214) in a review article also concluded that 6 weeks of NMES applied to the supraspinatus and posterior deltoid muscles enhanced the upper limb motor recovery in the early poststroke period. However, a recent study raises questions about the effect of shoulder NMES on motor recovery when applied in the acute poststroke period. Church et al. (215) studied the effect of shoulder transcutaneous NMES applied to stroke patients within 10 days poststroke. Significant differences were seen at 3 months in favor of the control group for specific measures of arm function and impairment including the grasp and gross movement subsections of the ARAT, Frenchay Arm Test, and the arm subsection of the Motricity Index. They concluded that the “routine” use of transcutaneous NMES to the proximal upper extremity after acute stroke could not be recommended. However, this study enrolled all stroke survivors regardless of presence or absence of subluxation, pain at baseline was not an inclusion criterion, they received substantially less NMES compared to previous

studies and outcome measures focused on distal hand function and were not specific to the proximal intervention.

Shoulder pain, distinct from shoulder subluxation, is a frequent poststroke complication that is associated with a reduced quality of life (216) for stroke survivors. The incidence of poststroke shoulder may be 40% within the first 6-months poststroke (217). A 72% incidence of shoulder pain was found in a series of 219 hemiparetic patients followed for 1-year poststroke (218). The majority of patients with poststroke shoulder pain rate the pain to be of moderate to severe intensity (219). The effects of TENS and transcutaneous NMES on poststroke shoulder pain have been explored. Linn et al. (211) found that 4 weeks of cyclic NMES applied within 48 hours poststroke reduced the shoulder pain and subluxation though the effect was not maintained beyond the treatment period. In a review article (220), four randomized trials (34,210,211,221) were evaluated that assessed various transcutaneous ES techniques applied at variable poststroke durations for prevention or treatment of shoulder pain. The authors concluded that ES did not affect pain incidence or intensity though ES improved pain-free range of passive humeral lateral rotation. More recently, Chantraine et al. (222) compared the effect of 5 weeks of transcutaneous NMES, applied within the first month poststroke, to conventional therapy in a nonrandomized controlled study of 120 patients with both pain and subluxation. In this study, the NMES group showed significantly more improvement than the control group on pain relief, reduction of subluxation, and recovery of arm motion.

Although data suggest that transcutaneous NMES reduces shoulder subluxation and improves pain-free range of motion, clinical implementation has been difficult due to the need for skilled personnel to ensure tolerable and reliable stimulation. In order to address this limitation, a percutaneous, intramuscular NMES system which includes helical intramuscular electrodes, a “pager” size stimulator, and connector wires has been trialed for the treatment of poststroke shoulder pain (Fig. 71-3). In a controlled clinical trial, Yu et al. (223) studied 61 chronic stroke survivors with shoulder pain and subluxation. The treatment group received percutaneous, intramuscular NMES to the supraspinatus, posterior deltoid, middle deltoid, and trapezius for 6 hours a day for 6 weeks. The NMES treatment group exhibited a significant reduction in shoulder pain, which persisted for 6 months posttreatment, as compared to controls. A follow-up study (224) found that pain reduction was maintained for  $\geq 12$  months posttreatment. Post-hoc analysis revealed that treatment within 18 months of stroke was a predictor of treatment success (225). A second percutaneous system under investigation is a miniature injectable microstimulator (BION, Alfred E. Mann Institute) which receives power and command signals from an external radiofrequency transmission coil (226). Clinical trials evaluating its efficacy for treating post-stroke shoulder dysfunction are ongoing.

In summary, the use of transcutaneous NMES can reduce shoulder subluxation, increase pain-free range of motion, and facilitate poststroke upper limb motor recovery in early stroke. Further studies are indicated to evaluate a potential detrimental

**FIGURE 71-3.** A percutaneous intramuscular ES system for treatment of hemiplegic shoulder pain. The pager size stimulator is connected to the implanted electrodes via a connector that can be disconnected when not in use. (RestoreStIM, courtesy, NeuroControl Corporation, North Ridgeville, OH.)

effect of shoulder NMES on motor recovery when applied in the immediate poststroke period ( $<10$  days). Clinical usage of transcutaneous NMES systems may be limited by issues of stimulation-induced pain, difficult access of deeper muscles, and inconsistent electrode placement; percutaneous systems may enhance repeatability and reliability. A percutaneous, intramuscular NMES, when applied to the supraspinatus, posterior deltoid, middle deltoid and trapezius muscles, can reduce shoulder pain for up to 1 year posttreatment. However, given its invasive nature, the superiority of percutaneous NMES over “best practice” and “usual care” in reducing poststroke shoulder pain needs to be demonstrated.

## SPINAL CORD STIMULATION

SCS has been used for more than 30 years to treat a variety of pain syndromes. Shealy et al. (227) first reported the modulation of pain associated with ES of the dorsal columns of the spinal cord in 1967. The analgesic effect of spinal epidural stimulation was subsequently reported by Shimoji et al. (228) in 1971. Lindblom et al. (229), in 1977, described the effect of single and repetitive ES of the dorsal columns on cells in laminae IV and V of the ipsilateral dorsal horn at S1 in an animal model. They noted that post-dorsal column stimulation suppression of pain appeared to be secondary to spinal mechanisms whereas longer-lasting pain relief appeared dependent on interneurons and suprasegmental loops. A dorsal column stimulator (DCS) is a specific implantable neuromodulation device used to treat chronic, intractable pain of neurologic origin. More recent human studies have demonstrated the clinical

efficacy of dorsal column stimulation in relieving specific chronic pain disorders including failed back syndrome, pain associated with SCI, complex regional pain syndrome (CRPS), and postamputation limb pain.

The proposed mechanism of action of SCS for reduction of neuropathic pain remains poorly understood. In an early animal model (230), DCS applied to the cervical and mid-thoracic levels depressed the activity of spinothalamic tract cells at the lumbosacral level for about 150 ms. In a study of the morphology of human superficial dorsal and dorsolateral column fibers at the lower thoracic spine (231), the mean A-beta fiber diameter, density and frequency increased significantly medially to laterally and the largest A-beta fibers were activated up to a maximum depth of about 0.25 mm. In a study of DCS in normal humans, Shimoji et al. (232) suggested that the pain-alleviating effect may be at least partly due to orthodromic and/or antidromic activation of descending inhibitory pathways which inhibit the transmission of pain signals by A delta and C fibers from the corresponding dermatome. A review of mechanisms of SCS (233) concluded that multiple mechanisms likely operate sequentially or simultaneously to relieve pain. These mechanisms may include antidromic activation of large-diameter afferent fibers (232), activation of supraspinal loops relayed by the brain stem or thalamocortical systems (234–237), activation of the anterior pretectal nucleus resulting in descending inhibition of pain (238–240), suppression of wide-dynamic-range neurons within the dorsal horn (241–243), and antidromic release of neuropeptides such as calcitonin gene-related peptide (244–246).

In clinical trials, the efficacy of SCS for chronic pain is generally assessed by a postimplantation reduction of pain of at least 50% and reduction of oral pain medication requirements. In a multiyear retrospective study, Kumar et al. (247) reported on the efficacy of epidural SCS in 121 subjects with chronic pain of various etiologies. Postimplantation, subjects were followed for periods ranging from 6 months to 10 years, with a mean follow-up period of 40 months. Forty-eight patients (40%) were able to control their pain by neurostimulation alone; 14 patients (12%) required occasional analgesic supplements, in addition to stimulation, to achieve 50% or more relief of the prestimulation pain. In a multicenter study of 90 patients implanted with a DCS for chronic pain of the back and/or legs, Shatin et al. (248) reported that 70% had “good” or “excellent” pain relief at an average of 14.5 months postimplantation. The percentage of patients requiring opioid medications decreased from 40% preimplantation to 28% postimplantation. Lastly, in a 5-year follow-up study of 50 patients implanted with a SCS for failed back syndrome (249), a minimum of 50% reduction in pain was recorded in 53% of patients at 2.2 years and in 47% of patients at 5-years postimplantation. Eighty-three percent of the subjects continued to use their stimulators at the 5-year follow-up. The percentage of patients using analgesic medication decreased from 74% preimplantation to 12% postimplantation. In a study evaluating patient satisfaction postimplantation (250), 60% of 41 patients considered themselves improved from their preoperative

condition and 78.1% of patients would recommend SCS to someone with a similar pain.

Other important outcome measures have been utilized in clinical SCS trials, including measures of impairment, activity limitation, and cost-effectiveness. In a prospective study of patients with intractable lower extremity pain who underwent SCS implantation (251), a statistically significant improvement in isometric lower extremity function 6 weeks postimplantation was found that persisted at both 12- and 24-months follow-up. Kemler and Furnee (252) randomized 54 subjects with CRPS to receive either SCS and PT or PT only. Pain, though not reflecting functional status or depression, improved significantly in the SCS+PT group at 6 months postimplantation. At 1 year, pain and quality of life were improved significantly only in the SCS+PT group. The cost effectiveness of SCS as compared to conventional therapy has been suggested in analyses of the long-term medical costs incurred for treatment of chronic pain (252–254).

The implantation of a DCS is a minimally invasive, reversible procedure (Fig. 71-4). Dorsal column stimulation can only be effective if dorsal column fibers in the spinal cord are preserved and can be stimulated by implantable electrodes. Thus, the implantation of a DCS involves two stages. In the first stage, a temporary percutaneous lead is placed and connected to an external pulse generator. If stimulation is effective in reducing pain by at least 50% over a period of 3 to 7 days, the patient is considered a candidate for the implanted SCS system. In the second stage, one or more epidural electrodes are inserted into the spinal canal over the dorsal aspect of the spinal cord. The implanted electrode may be placed via percutaneous insertion or may be surgically placed via a laminectomy. The spinal level for electrode placement is dependent on the location of the pain. There are several types of SCS implantable units including a conventional implantable pulse generator (IPG) (neurostimulator), rechargeable IPG, and a radiofrequency device. The radiofrequency device consists of an implanted receiver and transmitter device that utilizes radiofrequency to control stimulation. Postimplantation, the SCS system is programmed for the appropriate stimulation patterns and the patient is provided with a remote control to activate the stimulator. Complications of implantation are generally related to the surgical procedure itself and include infection, epidural hematoma, paralysis, and lead migration.

Successful reduction of pain, secondary to SCS, is highly dependent on patient selection; most candidates have previously failed conventional pain treatment modalities. Psychological factors may contribute to DCS failure which underscores the need for specific criteria for patient selection (255). Preoperative psychiatric evaluation and a trial of percutaneous DCS testing may be predictive of the individuals likely to have the greatest benefit (256). Multiple reviews (257–263) have summarized the efficacy of SCS for treatment of chronic pain associated with failed back syndrome, SCI, CRPS, postamputation limb pain, and other chronic pain syndromes. There is clear evidence that ES of the dorsal columns can modulate pain. In the

clinical care of chronic pain patients, SCS is a viable treatment option for select patients with intractable pain who have failed conventional management.

## DEEP BRAIN STIMULATION

DBS is a nonablative, reversible neurosurgical intervention for the treatment of Parkinson's disease (PD) and other neurologically based movement disorders. DBS of the thalamus

was first introduced in France in 1987 for essential tremor and was applied in 1993 to the subthalamic nucleus (STN) (264) for the treatment of PD (265). DBS involves the application of continuous low-voltage electrical impulses to targeted areas of the brain for the purpose of modulating dysfunctional brain signals. The most common sites of electrode implantation are the thalamus, STN, and globus pallidus (GP). For dystonia and symptoms associated with PD (rigidity, bradykinesia/akinesia, and tremor), the electrode is generally placed in either the GP or STN; for essential tremor, the electrode is

placed in the ventrointermedial nucleus (VIM) of the thalamus. The implantation of DBS electrodes is generally reserved for patients with advanced symptoms or symptoms which are poorly controlled with oral medication. Overall, DBS may reduce 50% to 60% of symptoms specific to PD though DBS does not affect the nonmotor symptoms of the disease such as balance instability, cognitive decline, and memory loss. A recent meta-analysis of outcomes following STN DBS for PD (266) found an average reduction in L-dopa equivalents of 55.9%, an average reduction in dyskinesia of 69.1%, and an average improvement in quality of life of 34.5%. DBS does not generally eliminate the need for oral medication but does reduce medication requirements that may significantly reduce common medication-related side effects. While DBS may provide symptomatic relief, it does not slow or reverse the neurodegenerative process of the underlying disease. Within the United States, the Food and Drug Administration (FDA) has approved DBS as a treatment for essential tremor (1997), PD (2002) and dystonia (2003).

The direct effect of DBS on the physiology of brain cells and neurotransmitters remains controversial though DBS is presumed to help modulate brain circuitry by sending electrical signals to target areas of the brain to inhibit dysfunctional signals (267,268). Vitek (270) noted that microelectrode recordings during DBS in a monkey model of PD suggest that ES of structures within the basal ganglia-thalamocortical circuit results in a change in neuronal output. In a review of mechanisms of DBS (270), both DBS and pallidotomy were noted to interrupt abnormal patterns of firing in cortico-basal ganglia-thalamocortical loops which are responsible for the symptoms of PD. Nonsynaptic mechanisms of efficacy have also been explored in a recent animal study (271). DBS increased astrocyte release of ATP, a precursor to adenosine, through a catabolic process within the thalamus. Adenosine A1 receptor activation, in turn, depressed excitatory transmission in the thalamus. In a study of 48 subjects with PD (272), an increase in regional cerebral blood flow (rCBF) was associated with STN DBS. Modest correlations were determined between motor symptoms and rCBF in specific regions of the thalamus, midbrain, and supplementary motor area (SMA). While recent review articles (267–270,273–275) have summarized the potential mechanisms of DBS, further research is indicated to better understand, present, and refine future therapeutic applications of DBS.

DBS requires the surgical implantation of a battery-operated neurostimulator that delivers continuous low-voltage electrical pulses to specific targeted areas of the brain. The DBS system consists of an electrode, an insulated extension wire, and a battery-powered implanted pulse generator (Fig. 71-5) (neurostimulator). The implantation of the stimulating electrodes is performed under local anesthesia. Computerized brain-mapping technology is used to map the precise location in the brain that generates the targeted symptoms (276). The electrodes are then connected via an insulated extension wire to an internal pulse generator (IPG) placed subcutaneously within the chest wall under general anesthesia. A magnet

**FIGURE 71-5.** Soletra neurostimulator (Medtronic). DBS system consists of a neurostimulator for controlled electrical pulse generation delivered by extension and lead(s) to the targeted structures deep within the brain. (Courtesy: Medtronic Corp.)

is used to adjust the stimulation parameters to provide the appropriate level of stimulation to optimize symptom suppression while minimizing the side effects. The patient can control the duration of stimulation via a handheld control device. The DBS system can be used to provide symptom relief for up to 24 hours a day.

There are potential complications associated with DBS (277). Complications specific to the surgical placement of the device include infection, mild disorientation or sleepiness, intracranial swelling, cerebrospinal fluid leak, or brain hemorrhage. Complications associated with the technical components of the device itself are relatively common. In a retrospective study of 84 patients (278), 25.3% of subjects experienced hardware-related complications with electrode connector issues being the most frequent problem. Similarly, a prospective study (279) found that 26.2% of DBS patients had hardware complications which included lead migration, lead fracture, extension erosion, extension fracture, and IPG malfunction. The potential risks associated with MRI imaging (280,281) and functional MRI imaging (282) in patients with DBS systems include excessive heating, electrode displacement (281), and/or functional disruption of the device. DBS patients may be safely imaged with MRI though specific guidelines for MRI usage in individuals with DBS systems are dependent on the IPG model and components. Neuropsychiatric side effects were described in a controlled

study of PD patients who underwent bilateral STN DBS (283). Six months postimplantation, declines were noted in verbal fluency, naming, selective attention, and verbal memory. Approximately, 9% of the STN patients had more serious psychiatric complications as compared to 3% of controls. In a more recent controlled study (284), DBS resulted in a selective decrease in frontal cognitive functions at 6 months post-implantation which did not negatively affect the quality of life. Lastly, a recent meta-analysis (285) concluded that there were relatively low rates of depression, cognitive impairment, mania, and behavior change but an increased rate of suicide in patients treated with DBS, particularly patients with STN and GP stimulation.

DBS has been proposed as a therapeutic intervention to promote late functional recovery following traumatic brain injury (286–291). In 2007, Schiff et al. (292) reported behavioral modulation associated with bilateral DBS of the central thalamus in a patient who remained minimally conscious 6 years following a TBI. Outcome measures included specific cognitively mediated tasks, functional limb control, and oral feeding. A statistical linkage between functional improvements and stimulation was determined. DBS is presently under investigation for the treatment of arm tremor in multiple sclerosis (293,294), major depression (295), Tourette's syndrome (286), epilepsy (296,297), obsessive-compulsive disorder (298,299), and neuropathic pain (300–302).

## CORTICAL ELECTRICAL STIMULATION

Several forms of cortical stimulation are being trialed as neuromodulation interventions to ameliorate symptoms of neurologic disease. The three most common types of cortical stimulation are transcranial magnetic stimulation (TMS), transcranial ES (using pulsed or direct current), and epidural cortical stimulation (ECS) using surgically implanted electrodes (303). In contrast to DBS, the efficacy of cortical stimulation to treat neurologic disorders has not yet been definitively established and many research questions remain unanswered regarding the mechanisms of therapeutic efficacy, modes of stimulation, relevant neurologic diagnoses, and meaningful motor impairment, activity limitation, and quality of life outcome measures.

TMS was developed in 1985 as a noninvasive method of exciting cortical neurons using electromagnetic induction. Rapidly changing magnetic fields are applied transcranially to induce focused electric currents in the underlying cerebral cortex using an electromagnetic coil (round, figure-eight or double-cone configuration) applied directly to the scalp. With stereotactic MRI-based control, the precision of targeting TMS can be approximated to a few millimeters (304). Repetitive transcranial magnetic stimulation (rTMS) is being trialed as a method to induce sustained therapeutic effects in patients with movement disorders (305), stroke (306), neuropathic pain (303,307), depression (308), and various neuropsychiatric disorders. By manipulating stimulation frequency, intensity and coil orientation, rTMS is presumed to influence

the excitability of cortical pathways by altering synaptic transmission (309). Low frequency (1 Hz) rTMS decreases brain activation while stimulation at higher frequencies (>5 Hz) increases brain activation. A rare but present risk of TMS is induction of a seizure. In depression studies, no cognitive side-effects including memory loss, concentration difficulties or loss of other cognitive capacities have been reported. Multiple recent reviews (305,310–312) have summarized the theoretical basis of TMS and research and potential therapeutic clinical applications of TMS.

Transcranial direct current stimulation (tDCS) is the noninvasive application of weak direct currents to induce sustained changes in cortical activity and excitability via the hyper- or depolarization of resting membrane potentials (313). Transcranial DCS has been demonstrated to influence the excitability of the human motor cortex in research applications (314,315). In a study of seven healthy adults, Vines et al. (316) found that stimulating a motor region directly, or indirectly by modulating activity in the homologous region on the opposite hemisphere, affected the motor skill acquisition by a proposed mechanism of facilitating synaptic connectivity. Lang et al. (317) studied the effect of tDCS of the primary motor cortex on regional neuronal activity in a controlled study of 16 healthy volunteers. When compared to sham tDCS, 10 minutes of anodal and cathodal tDCS induced widespread changes in cortical and subcortical rCBF as measured by positron emission tomography (PET) scanning. The therapeutic application of tDCS is being investigated for various neurologic disorders including movement disorders (318), motor recovery poststroke (319), epilepsy (320), depression (321,322), and tinnitus (323). Recent reviews (2,313,324) provide an overview of present understanding and potential applications of tDCS. At present, tDCS is limited to research applications but appears to be a promising neuromodulatory technique that may ultimately benefit the field of clinical neurorehabilitation.

ECS is a minimally invasive technique which involves the application of low-voltage, high frequency stimulation to the motor cortex via chronically implanted epidural electrodes. ECS was first described by Tsubokawa et al. (325,326) for treatment of central (thalamic) and neuropathic pain. Since then, ECS has been demonstrated to be effective for pain associated with trigeminal neuropathy, lateral medullary and thalamic infarction, anesthesia dolorosa, postherpetic neuralgia, SCI, and postamputation phantom pain (327). Preoperative fMRI, 3-dimensional volume MRI, neuronavigation and intraoperative neurophysiological monitoring have improved the technique for identifying the targeted motor cortical area and for optimum placement of the electrode array (328). Once the epidural electrode has been activated, stimulation-induced pain relief may occur within minutes, with pain relief lasting up to hours following discontinuation of ECS (327). In a study of the effect of ECS on neuropathic pain, Drouot et al. (329) suggested that ECS acts on neural pathways involved in sensory discrimination to modulate transmission of pain signals. Saitoh et al. (330) found an increase in rCBF in the contralateral thalamus following motor cortex stimulation in a

patient with poststroke pain. Similarly, Brown (327) proposed that the efficacy of ECS in central pain is based on an increase in rCBF in the cingulate gyrus and the ipsilateral ventrolateral thalamus in which corticothalamic connections from the motor and premotor areas predominate. A recent review (328) concluded that ECS is increasingly reported as an effective surgical option for the treatment of various forms of refractory neuropathic pain.

Recently, there has been interest in ECS as a treatment for movement disorders such as PD, particularly for patients who are excluded from the more invasive DBS procedure. The first application of chronic epidural motor cortex stimulation for PD was reported by Canavero and Paolotti (331) in 2000. In an animal model of PD (332), exposure to intermittent, high intensity cortical stimulation of the primary motor cortex via epidural electrodes resulted in a temporary reduction in the severity of PD symptoms. In a human study (333), 16 subjects with PD who underwent ECS via chronically implanted electrodes demonstrated sustained improvement of a broad spectrum of symptoms including tremor, rigor, akinesia, axial symptoms, speech and swallowing, and reduction in levodopa dosage. A recent review of extradural cortical stimulation for movement disorders concluded that potential mechanisms of action of ECS in PD include “hyperdirect” motor cortex-STN input, inhibition, resynchronization, plasticity changes, inter-hemispheric transfer of inhibition/excitation and modulation of other cortical areas (334). Important unresolved issues for broader clinical application of ECS in PD include optimal electrode position and stimulation parameters, the benefit of unilateral versus bilateral stimulation, and refinement of patient selection criteria (335).

ECS is also being studied for its ability to affect neuroplasticity to facilitate poststroke motor recovery (336). In an animal model, Adkins et al. (337) implanted chronic epidural electrodes over the motor cortex of animals that had sustained a subtotal ischemic lesion of the sensorimotor cortex. The animals were divided into two subgroups based on the level of motor impairment and randomized to receive 18 days of rehabilitative training with either 100 Hz cathodal ECS at 50% of movement thresholds or no stimulation. ECS partially normalized the movements, and a significantly greater density of axodendritic synapses was noted in both impairment subgroups in the ECS group as compared to the no stimulation group. The moderately impaired ECS animals had increases in presumed efficacious synapse subtypes (perforated and multiple synapses) as compared to the no stimulation group. Synaptic density was positively correlated with postrehabilitation reaching success. The authors suggested that ECS promoted functional recovery and that ECS-induced functional improvements may be mediated by synaptic structural plasticity in stimulated cortex. Early human studies demonstrated the feasibility of ECS among chronic stroke survivors (338). A follow-up phase II RCT by Levy et al. (339) suggested efficacy with improvements in upper limb motor impairment and activities limitation. However, the Everest Clinical Trial (340), a phase III RCT to test safety and efficacy of ECS delivered

during rehabilitation for upper limb motor function, failed to corroborate earlier findings.

## CONCLUSION

In this chapter, we have summarized the history, mechanisms, and clinical applications of ES to treat the neurologically based disorders most commonly encountered in the clinical practice of Physical Medicine and Rehabilitation. The application of ES to treat neurologic disease has a long history dating to ancient Egyptian times. Present day clinical applications of ES are broadly defined as providing either a therapeutic or functional benefit. The goal of therapeutic ES is to achieve a sustained effect that persists beyond the period of intervention. Within the field of Physical Medicine and Rehabilitation, therapeutic ES is commonly prescribed to both decrease the impairment and prevent further impairment and activity limitation associated with immobility or disuse of a limb or organ system.

At the dawn of the 21st century, the efficacy and safety of therapeutic ES has been established in a variety of neurological disorders including chronic pain, paralysis, and movement disorders. Therapeutic ES has the capacity to treat disease, decrease impairment, and enhance quality of life for patients who have sustained neurologic injury. The establishment of therapeutic efficacy of a broad spectrum of transcutaneous ES devices as well as implanted neuroprostheses and neuromodulators clearly expands the armamentarium of the physiatrist in the clinical care of patients. Future research will undoubtedly focus on further defining the patient populations, applications and mechanisms by which ES may impart therapeutic benefit. Ongoing basic science and clinical research offers promise for therapeutic benefit of ES for an even broader spectrum of neurologically based disorders.

## ACKNOWLEDGMENTS

The preparation of this chapter was supported, in part, by the National Institute of Child Health and Human Development (NICHD), grant K24HD054600.

# Functional Neuromuscular Electrical Stimulation

## INTRODUCTION

Neuromuscular electrical stimulation (NMES) refers to the use of low-level electrical current to produce a muscle contraction. In the field of Physical Medicine and Rehabilitation, NMES is used in cases of neurological injury that result in muscle paralysis or paresis. Clinical applications of NMES provide either a therapeutic or functional benefit. Therapeutic NMES applications are intended to reduce specific impairments or to induce or hasten the recovery of volitional motor function and, therefore, are temporary or periodic interventions. Usually, therapeutic NMES applications do not directly provide motor function; provision of motor function is the purpose of *functional* NMES applications, which are the focus of this chapter. Functional NMES applications produce coordinated contractions of multiple muscles that enable the motor-impaired individual to accomplish functional tasks directly. A functional NMES device is called a *neuroprosthesis*, because it substitutes for or replaces lost neuromuscular function and is considered to be an ongoing or permanent intervention. Ideally, a neuroprosthesis should be easy to wear all day so that its utility is available whenever needed. This chapter reviews the principles of NMES and neuroprosthetic systems for several functional NMES applications.

## PRINCIPLES OF NMES

### Electrical Activation of the Neuromuscular System

Action potentials, and therefore muscle contractions, can be generated with electrical current. Electrical current, applied to excitable tissue through a pair of electrodes, creates a localized electric field that depolarizes the axonal membranes of nearby neurons. If the depolarization reaches a critical threshold, an influx of sodium ions from the extracellular space to the intracellular space produces an action potential that propagates from the site of stimulation and has the same effect as a naturally generated action potential. When the action potential reaches the terminals of the axon, neurotransmitter is released and, in the case of motor neurons, muscle fibers contract.

NMES systems generally operate by activating motor neurons rather than the muscle directly, even though NMES

is commonly referred to as “muscle stimulation.” It is easier to stimulate a nerve than a muscle. The stimulus threshold for a neural tissue, the lowest level of charge that will generate an action potential, is much less than the threshold for muscle fibers (1). While it is possible to generate action potentials in muscle fibers directly, it is not usually done because of power consumption considerations. *This means that for NMES to be applicable in a given patient, their lower motor neurons must be intact from the anterior horns of the spinal cord to the neuromuscular junctions of the target muscles.*

Damage to lower motor neurons prevents the successful application of NMES in patients with polio, late-stage amyotrophic lateral sclerosis (ALS), and peripheral nerve injuries (e.g., brachial plexus injury). In addition, patients with disorders at the neuromuscular junction or muscle tissue (e.g., muscular dystrophies) are ineligible for NMES applications. NMES may be used when the lower motor neurons are excitable and the neuromuscular junction and muscle are healthy, as is usually the case in patients with spinal cord injury (SCI), stroke, traumatic brain injury, cerebral palsy, or multiple sclerosis. To date, most motor neuroprostheses have been targeted toward the SCI population.

Large axons are easier to stimulate than small axons. Large-diameter axons, which innervate the larger motor units, have lower stimulus thresholds than small-diameter axons (2). This is because the wider spacing between the nodes of Ranvier in large axons produces larger induced transmembrane voltage changes. The activation of large motor units before small motor units is known as reverse recruitment order and is the opposite of the physiological size principle, where small motor units are initially recruited, followed by larger motor units. In spite of this reverse recruitment order, it is still possible to produce graded muscle contractions with NMES.

Because large-diameter axons have lower stimulus thresholds, type II muscle fibers (fast-fatiguing) are preferentially recruited over type I muscle fibers (fatigue-resistant). Fatigue resistance is highly desirable for most functional NMES applications. Unfortunately, disuse atrophy tends to convert type I to type II fibers (3). However, long-term use of NMES can reverse muscle atrophy and convert type II fast-fatiguing fibers to type I fatigue-resistant fibers (4,5). Therefore, all current neuroprosthetic NMES applications use some form of muscle conditioning regimen to build and maintain fatigue-resistant muscle.

Axons near the stimulus source are easier to stimulate than axons farther away. The electric field diminishes with distance from the stimulus source; as the distance between the electrode and the axonal fiber increases, the stimulus threshold also increases (1). Less current is required to stimulate neurons in the proximity of the stimulating electrode because the transmembrane potentials generated by the electrical current are largest in the axons close to the stimulating electrode. Therefore, to improve the selectivity of stimulation, electrodes are placed as close as possible to target muscles or nerves.

The strength of a muscle contraction produced by NMES can be modulated by manipulating three stimulus parameters that characterize the wave of current pulses: pulse frequency, amplitude, and duration. If the pulse frequency is too low, the muscle responds with a series of twitches. As the pulse frequency is increased, the twitches begin to overlap and build on one another, producing a smooth or “fused” contraction. This cumulative effect of repeated stimulus pulses within a brief period of time is known as *temporal summation*. Higher stimulus frequencies produce stronger muscle contractions up to a maximum, but also make a muscle fatigue more rapidly than lower-frequency stimulation. Therefore, the ideal stimulus frequency is the lowest frequency that will produce a fused contraction, and depends on the muscle fiber type and the manner in which the stimulation is being delivered (e.g., surface vs. implanted electrode). In upper extremity applications that use implanted electrodes, a stimulus frequency of 12 to 16 Hz has been found to be the minimum required for producing fused contractions if the muscles have been conditioned to have relatively long-duration twitches. The strength of a muscle contraction may also be increased by increasing the pulse amplitude and/or pulse duration, which effectively increases the electric charge per pulse (6). The greater the electric charge, the larger the electric field and broader the region of activation. In this way, more axons and more motor units are activated, an effect known as *spatial summation*. In most neuroprostheses, the strength of muscle contraction is controlled by modulating the pulse amplitude or pulse duration while keeping the pulse frequency constant and as low as possible to avoid premature fatigue of muscles.

### Safe Stimulation of Living Tissue

Safe stimulation waveforms and electrode materials have been experimentally established. For NMES applications using implanted electrodes, a *current-regulated* stimulator with a *balanced biphasic* stimulus waveform should be used. With implanted electrodes it is important to use stimulus parameters (pulse amplitudes and durations) that are appropriate for the dimensions and material composition of the electrode so that the charge density per phase remains within the established safe limits, thereby preventing electrode corrosion or dissolution of metal ions (1). With current-regulated stimulation, the current is directly controlled (current is the charge delivered per unit time). Therefore, the quantity of charge delivered per stimulus pulse can be maintained within safe limits. Improper stimulation can also cause tissue damage by producing irreversible

electrochemical reactions at the electrode-tissue interface. Irreversible reactions can be avoided with charge-balanced biphasic stimulus waveforms. Biphasic waveforms consist of a repeating current pulse that has a cathodic (negative) phase followed by an anodic (positive) phase. The first, or primary, phase elicits an action potential in nearby axons, and the secondary positive pulse balances the charge of the primary pulse. The purpose of the secondary pulse is to reverse the potentially damaging electrochemical processes that occur at the electrode-tissue interface during the primary pulse, allowing neural stimulation without causing tissue damage (1).

For NMES applications using surface electrodes, other safety factors need to be considered. For example, the electrode-tissue contact area is often not a constant as surface electrodes often pull away from the skin or dry out. If a current-regulated stimulator is used in this circumstance, the reduction in contact area will cause high current densities and can result in burning the skin and underlying tissue. However, with a *voltage-regulated* stimulator, the magnitude of current delivered to the tissue is dependent on the impedance at the electrode interface (current = voltage/impedance). If the impedance at the electrode-skin interface increases because the electrode dries or loses strong contact with the skin, then the current delivered will decrease, thereby reducing the possibility of skin burns due to high current densities. Although this may be safer, a major disadvantage of voltage-regulated stimulation is that the muscle contraction produced is more variable because the changes in impedance lead to changes in applied current. Regardless of whether current- or voltage-regulated stimulators are used, even with good electrode-skin contact, burning of the tissue can occur if the current densities are too high. Therefore, surface stimulation should be used with caution and with frequent examination of the skin when applied to patients with impaired sensation or cognition. Table 72-1 summarizes the principles of NMES and their practical ramifications when applying NMES systems.

### NMES System Configurations and Electrode Types

At least two electrodes are required to produce a current flow in NMES applications. One electrode, often referred to as the active electrode or cathode, is placed near the peripheral nerve or muscle motor point to be stimulated. The other electrode, known as the return electrode or anode, may be placed in a remote area near less excitable tissue (such as tendon or fascia), or it may be positioned close to the active electrode to confine the electric field to a small region of activation and thereby achieve more selective muscle activation. Additional electrodes are needed to achieve coordinated activation of multiple muscles. Multichannel NMES systems stimulate multiple muscles simultaneously and use either a bipolar or monopolar arrangement of electrodes. Bipolar multichannel systems require a return electrode for each active electrode; so for each muscle or nerve to be activated, a pair of electrodes (cathode and anode) is needed. This bipolar arrangement may allow greater selectivity of activation (7), but requires more electrodes and leads. Monopolar electrode systems reduce the number of electrodes and leads by

**TABLE 72.1** Principles of Safe Electrical Activation of the Neuromuscular System and Practical Ramifications

Principle	Practical Ramification
Action potentials can be produced by NMES. It is easier to stimulate nerve than muscle.	Paralyzed muscles can be made to contract. NMES is generally applicable only to patients with intact lower motor neurons.
Large axons are easier to stimulate than small axons.	A muscle conditioning regimen is needed to build and maintain fatigue-resistant muscle.
Axons near the stimulus source are easier to stimulate than axons farther away.	Selectivity of stimulation is improved by placing electrodes close to the target muscles or nerves.
Applying closely spaced stimulus pulses to a muscle produces an overlapping of muscle twitches, resulting in a “fused” contraction— <i>temporal summation</i> .	The strength of a muscle contraction can be modulated by increasing or decreasing the stimulus pulse frequency. However, very high stimulus frequencies cause rapid muscle fatigue.
More axons and motor units of a muscle are activated when the size of the electrical field is increased by increasing the electric charge per stimulus pulse— <i>spatial summation</i> .	The strength of a muscle contraction can be modulated by increasing or decreasing the stimulus pulse amplitude and/or duration.
With implanted electrodes, electrode corrosion can be avoided by maintaining the charge density per phase of stimulus pulse within safe levels determined for the particular electrode material composition and dimensions.	Current-regulated stimulators should be used with implanted electrodes.
With implanted electrodes, tissue damage can occur if irreversible electrochemical reactions are produced at the electrode-tissue interface.	Charge-balanced biphasic stimulus waveforms should be used with implanted electrodes.
With surface electrodes, high current densities can cause skin burns.	Surface electrodes that maintain good contact with the skin should be used. Extra caution is needed when applying NMES to patients with reduced sensation or impaired cognition.

using only one remote return electrode with an active electrode placed near each motor point or nerve targeted for excitation.

Functional NMES systems consist of at least three components: electrodes, a multichannel stimulator, and a controller (Fig. 72-1). The electrodes deliver the electrical

**FIGURE 72-1.** Block diagram of a basic motor system neuroprosthesis.

current pulses to the excitable tissue, the stimulator generates the current waveforms for multiple cathodes, and the controller regulates the stimulation according to the user's intent. A controller may be as simple as a switch that the patient hits to turn the stimulation on and off, or may incorporate sensors for recording patient-elicited biopotentials (e.g., EMG or EEG) and use those as signals to regulate the stimulation. Depending on the way these three components are arranged with respect to one another, NMES systems can be categorized as surface, percutaneous, or implanted. In surface systems, the electrodes, the stimulator, and the controller are external to the body. In percutaneous systems, the electrodes are implanted near a muscle or nerve with leads that pass through the skin to an external stimulator with a separate or integrated external controller. In implanted systems, the electrodes and stimulator are implanted and the controller components are either all external or some are implanted and some are external. To date, there is no neuroprosthesis available that has all three components completely implanted, although several research programs are moving in that direction (8,9).

Surface NMES systems (sometimes called transcutaneous systems) use electrodes that are placed on the skin and connected with flexible cables to a stimulator, which may be worn around the waist, the arm, or the leg. Usually, a sensor or switch that controls the stimulation is also connected to the stimulator. Surface electrodes are readily available in a variety of sizes from many manufacturers. The electrodes are placed on the skin over the nerves or over the “motor points” of muscles

to be activated. The motor point is the site of stimulation that produces the strongest and most isolated contraction at the lowest level of stimulation. Surface NMES systems offer several distinct advantages: (a) the electrodes are generally easy to apply and remove, (b) the stimulation technique is noninvasive and therefore reversible, (c) the use of surface electrodes can be readily learned and applied in the clinic, and (d) stimulators and surface electrodes are relatively inexpensive and commercially available. Stimulation with surface electrodes is the most widely used technique for therapeutic applications, and has been successfully employed to produce standing, stepping, and grasping motions. However, there are several disadvantages to using surface NMES systems: (a) they cannot produce isolated contractions of small or deep muscles, (b) movement of the target muscle under the skin as the stimulated limb moves can change the proximity of the electrode to the target muscle/nerve, resulting in inconsistent muscle contraction and force production, (c) daily doffing and donning the electrodes can complicate use, especially if electrode positions vary slightly from day to day, (d) in many cases, cutaneous pain receptors are stimulated and patients with preserved or heightened sensation may find it difficult to tolerate, and (e) the system may draw unwanted attention, especially if there are multiple stimulus channels and many cables. These disadvantages have motivated the design of systems with implanted electrodes.

Percutaneous systems use electrodes that are implanted into muscles or near nerves, and have leads that pass through the skin and connect to an external stimulator. Percutaneous electrodes can activate deep muscles, can provide isolated and repeatable muscle contractions, and are less likely to produce pain during stimulation because they bypass the sensory afferents in the skin. Percutaneous electrodes are often formed from a multifilament lead within a single insulator that is wound into a helical configuration to produce maximum flexibility (10,11). Percutaneous intramuscular electrodes are inserted into the target muscle with a hypodermic needle. The needle is withdrawn, leaving the electrode in place and the lead exiting the skin. The exit sites on the skin are protected with a bandage and must be cleaned, dressed, properly inspected, and maintained to reduce the risk of complications (12). A large surface electrode is often used as the return electrode. Percutaneous systems provide a minimally invasive technique for investigating the feasibility of restoring functional muscle contractions without having to prematurely subject research participants to implantable system surgery. Percutaneous systems have served as precursors to fully implanted systems (13) and have provided function in some individuals for periods of years (14). Various studies have reported on the longevity of percutaneous electrodes (11,12,15–17). Although the failure rate due to breakage is low during the first few months post implantation, the cumulative 1-year failure rate can vary between 56% and 91% (12,17), but this depends on many factors including the type of percutaneous lead, lead-routing technique, and the muscles implanted. Other potential complications of percutaneous electrodes include formation of granulomas from retained electrode fragments and electrode-related infections,

which are treated with oral antibiotics or minor outpatient surgical procedures (12).

Implanted NMES systems are designed for long-term use. Both the electrodes and the stimulator are implanted, but the controller is external for most implanted systems, to date. Communication between the controller and stimulator is through radio-frequency (RF) transmission; therefore, no leads pass through the skin. Because the stimulator both receives RF commands and generates stimulus pulses, it is often called a receiver/stimulator. Implanted electrodes with insulated lead wires are connected directly to the implanted stimulator with inline connectors, which permit the surgical removal and replacement of individual electrodes, if necessary, without removing the stimulator. The electrode leads are larger than percutaneous leads because they need to be more robust and resistant to failure given the intention to make long-term use of them. In most implanted system configurations the circuitry of the stimulator is sealed in a titanium enclosure, which serves as the return electrode. Depending on the application, the stimulator is implanted in the upper chest or abdomen. The stimulator receives power and control instructions through RF telemetry from an external controller. The RF link allows the stimulator to be fully passive with no active battery, thereby eliminating the need for replacement of the implanted stimulator because of battery failure. The telemetry link requires no wires through the skin; rather, a circular coil (antenna) connected to the controller with a cable is taped to the skin over the implanted stimulator. The controller receives information from the user through switches, sensors, an implanted joint angle sensor, or biopotential electrodes to determine the user's intention and deliver stimulation accordingly. The controller may be worn on the body or carried on a user's wheelchair. For long-term clinical application, implanted systems provide major advantages over other systems including improved convenience, cosmesis, reliability, and repeatability.

A variety of electrodes may be used with implanted NMES systems (Fig. 72-2). Epimysial electrodes are sutured directly to the epimysium on the muscle surface (18); intramuscular electrodes are inserted directly into a muscle belly (19); epineural electrodes are sutured to the connective tissue surrounding a motor nerve (20); and nerve helix or cuff electrodes are implanted around a nerve (21–24). Epimysial electrodes have proved to be durable in upper and lower extremity applications (25,26), and are especially useful for activating broad, superficial, or thin muscles. Intramuscular electrodes allow activation of deeper or smaller muscles, such as the intrinsic muscles of the hand. Nerve-based electrodes are used when it is difficult to access the target muscle directly or when more complete muscle recruitment can be obtained by stimulating the nerve (27).

A unique configuration of implanted NMES system is the injectable microstimulator (BION), which is presently undergoing clinical trials for various therapeutic and neuroprosthetic applications (28). The BION (developed at the A.E. Mann Institute at the University of Southern California) is a small cylindrical (2 mm outer diameter × 16 mm length), injectable,

**FIGURE 72-2.** Electrodes used with implanted NMES systems. From L to R, epimysial stimulating electrode, intramuscular stimulating electrode, spiral nerve cuff stimulating electrode, epimysial EMG recording electrode. (Courtesy of the Cleveland FES Center, Cleveland, OH.)

single-channel unit that functions as a receiver/stimulator and electrode (29). BIONs are implanted with a 12-gauge trochar in target muscles or near target nerves; the quantity to be implanted depends on the application. An external RF coil transmits power and control information from an external control unit. Battery-powered BIONs and EMG-sensing micro-injectable units are presently under development.

These technologies and principles of electrical stimulation form the foundation for clinical applications of NMES. The next section will describe neuroprosthetic systems that have been developed for different upper motor neuron impairments.

## CLINICAL APPLICATIONS OF NMES

This section describes the neuroprosthetic systems for four different clinical applications: upper extremity function, lower extremity function, respiratory function, and bladder and bowel function. These four applications are the most developed, have undergone the most clinical testing, and have several different device options available or in development. For each application, the purposes, indications, and specific neuroprosthetic systems will be described. This is not an exhaustive review of every device that has appeared in the research literature, rather only those systems that have undergone clinical trials and are currently commercially available or devices that are currently in the clinical trial phase of development (i.e., may be available through participation in research) will be discussed and are summarized in Table 72-2 at the end of this section.

Finally, for each application, new technology developments and future research directions will be outlined.

### Upper Extremity Function

The purpose of upper extremity neuroprosthetic systems is to enable individuals to use their paralyzed or paretic arm and hand to perform activities of daily living (ADL) (e.g., eating, personal hygiene, etc.). In particular, these systems provide the ability to grasp and release with the impaired hand and thereby reduce the need of individuals to rely on assistance from others and reduce the time and effort required to perform a task. In addition to hand grasp and release, emerging systems are incorporating elbow extension with shoulder abduction and flexion to provide reaching ability to individuals with proximal and distal upper limb paralysis.

Upper extremity systems may be applicable to people with partial or complete paralysis of the arm and/or hand resulting from cervical SCI or stroke. The hand and forearm muscles targeted for stimulation must not be denervated, that is, the lower motor neurons must be intact. Many persons with C5 and C6 level tetraplegia have preserved lower motor neurons from C7 and C8 neurological segments and may benefit from upper extremity NMES systems that restore grasp and release. Persons with C4 or higher level tetraplegia who have C5 and C6 lower motor neurons preserved may benefit from NMES systems designed to provide shoulder stability and control of elbow flexion and extension, in addition to providing grasp and release. Any joint contractures must be corrected or functional ability will be limited. Spasticity and hypertonia must be under control. The best candidates are individuals with intact cognition, who are motivated, and desire greater independence. In addition, many neuroprosthetic systems require assistance in donning the device, so it may be necessary for the individual to have good attendant support.

The first upper extremity neuroprostheses were developed in the 1960s using surface electrodes, in combination with a flexor hinge splint to open and close the hands of individuals with cervical SCI (30,31). These case studies were followed by work with stroke survivors in the 1970s (32,33). One- and two-channel stimulators activated the finger and thumb extensors and triceps (in some subjects) when the individual elevated their opposite shoulder, a movement that was picked up by a shoulder-mounted transducer. These pioneering efforts have led to the development and clinical testing of several upper extremity neuroprostheses for stroke and spinal cord injured patients (34–41), some of which have been primarily intended for use as temporary therapeutic devices (see Chapter 71).

The NESS H200 (formerly known as Handmaster) is the only commercially available upper extremity neuroprosthesis (Bioness Inc., Valencia, CA) at the time of this writing. The H200 was originally developed for tetraplegia (42), but is also applicable to stroke survivors (43). The device is a wrist-forearm orthosis (Fig. 72-3), with five embedded surface electrodes that provide patterned stimulation to the finger and thumb flexors and extensors to produce selected hand movements. The

510(k): Also known as a premarket notification, the applicant has demonstrated that the device to be marketed is at least as safe and effective, that is, substantially equivalent, to a legally marketed device that is not subject to PMA, and therefore has been cleared to market the device.

IDE: Investigational device exemption allows an investigational device to be used in a clinical study in order to collect safety and effectiveness data required to support a premarket approval (PMA) application or a Premarket Notification (510(k)) submission to FDA.

PMA: Premarket approval, the FDA process of scientific and regulatory review to evaluate the safety and effectiveness of Class III medical devices. (Class III devices are usually those that support or sustain human life, are of substantial importance in preventing impairment of human health, or which present a potential, unreasonable risk of illness or injury.) PMA is the most stringent type of device marketing application required by FDA.

<sup>a</sup>FDA: Food and Drug Administration—agency of the United States Department of Health and Human Services that approves medical devices for research and marketing before they are made available to the public.

<sup>b</sup>CE Mark: a mandatory European marking for certain product groups to indicate conformity with the essential health and safety requirements set out in European Directives; indicates that the product may be legally placed on the market within the European Free Trade Agreement (EFTA) and European Union (EU) single market (total 28 countries).

<sup>c</sup>IDE applied to Version 1.0 of the Atrostim device.

orthosis is connected by a flexible cable to a portable external control unit with push-button controls. The user initiates pre-programmed opening/closing stimulation sequences by pressing buttons on the control unit. The orthosis fixes the wrist in neutral, making it applicable primarily to persons with C5 complete tetraplegia who do not have a tenodesis grasp. In a study of seven subjects with C5 or C6 tetraplegia, the system was used at home to practice three ADL for 3 weeks (44). At the end of the 3 weeks, all seven subjects could use the system successfully to perform ADL that they were unable to perform without the system. Similar results were achieved in a study of H200 with 29 stroke survivors (43). Long-term use of H200 as a neuroprosthesis has not been reported. The H200 has received Food and Drug Administration (FDA) clearance (510(k)) for marketing as providing hand function to stroke survivors or individuals with C5 SCI.

The implanted stimulator-telemeter 12 channel (IST12) system is an implanted upper extremity neuroprosthesis that

is presently used in clinical trials conducted by researchers at Case Western Reserve University in Cleveland (45). This group has been developing implanted upper extremity neuroprostheses for SCI patients since 1986, when they implemented the first implanted hand grasp system. The IST12 system is an advanced version of the Freehand system, which underwent extensive assessment of clinical outcomes, received FDA approval (premarket approval, PMA) for use in C5 and C6 tetraplegia, and was commercially available from 1997 to 2002. Like the Freehand system, the IST12 system consists of a receiver/stimulator that is surgically implanted in the upper pectoral region and epimysial, and intramuscular electrodes that are implanted at the motor points of hand and forearm muscles with leads that are routed subcutaneously to the stimulator (Fig. 72-4). The external components include a RF transmitting coil that is taped to the chest over the stimulator and connected to a programmable external control unit. This implanted system approach was shown, in the

**FIGURE 72-3.** The NESS H200 system. (Copyright 2007 Bioness, Inc., Valencia, CA.)

multicenter clinical trial of the Freehand system, to be successful in significantly reducing upper extremity impairment and activity limitation (46), and to be well accepted by the recipients (47), with very low rates of infection (<2%) and implant or electrode failure (<1%) (25).

The IST12 system builds on the clinical success of its predecessor, the Freehand system, by providing additional upper limb function and incorporating implanted EMG control methods. Enhanced function is achieved through additional stimulation channels. The Freehand system had eight stimulus channels (48); the IST12 system has 12. The additional channels are used to activate hand intrinsic muscles, triceps, or pronator quadratus. These additional muscles have resulted in better hand opening, improving object acquisition and release; elbow extension, increasing the user's workspace; and forearm rotation, improving the user's ability to optimally orient the hand. In the original Freehand system, the user controlled the opening and closing of their paralyzed hand by moving their opposite shoulder, which required wearing an external shoulder-mounted transducer. With the IST12 system, EMG control strategies are available, where the use of EMG signals are recorded from muscles that the patient still retains the ability to contract and relax. The EMG signals are picked up by implanted EMG-recording electrodes, a strategy that eliminates the need for donning an external sensor and opens the possibility of achieving more natural and intuitive control. Potential control muscles include those that are synergistic to the grasp movement, such as wrist extensors and, to a lesser extent, the brachioradialis, and nonsynergists such as sternocleidomastoid, trapezius, deltoid, platysma, or auricularis. Because the EMG control strategy makes use of muscle signals derived from the ipsilateral side, it allows the neuroprosthesis to be implemented bilaterally, which provides significant additional function to patients with tetraplegia.

The IST12 system is undergoing clinical testing; to date, 15 individuals with tetraplegia have received the system. Four of these participants have two systems implanted, one for each upper limb, in order to enable bimanual task performance. The longest follow-up has been 7 years. The functional results show that the neuroprosthesis provides significantly increased pinch force and grasp function for each subject (45).

**FIGURE 72-4.** IST12 system for upper extremity function. (Courtesy of the Cleveland FES Center, Cleveland, OH.)

All subjects have demonstrated increased independence and improved function in ADL. Thus far, the IST12 system has been implemented mainly in individuals with C5 or C6 SCI; clinical studies have also begun to evaluate the IST12 in patients with higher spinal cord injuries and in stroke survivors with chronic upper extremity hemiplegia and minimal flexor muscle hypertonia.

### Future Directions

Current research in upper extremity neuroprostheses focuses on stimulation of additional muscles, evaluation of new control methods, and incorporation of advanced technologies in order to provide additional function, broaden the clinical indications, and facilitate clinical implementation. Patients with C4 and higher levels of SCI need proximal arm control and hand control. Several case studies using percutaneous or surface stimulation of shoulder and elbow, and forearm and hand muscles, have been conducted to test the feasibility of a neuroprosthesis that restores function to the entire upper limb (49–51). Recently, a patient with high level tetraplegia resulting from a C1 Brown Sequard SCI was implemented with two IST12 implants to produce hand, elbow, and shoulder movements that enable basic daily tasks such as eating and grooming (52). Nerve cuff electrodes are used to stimulate elbow and shoulder muscles, and EMGs from neck and shoulder muscles are recorded with implanted electrodes and used as control signals. The cuff electrodes have exhibited excellent and stable performance for more than 1 year. Extensive functional assessment of this system is underway.

As researchers strive to develop NMES systems that are applicable to individuals with higher SCIs, the need for strategies that allow the user to naturally control the entire upper arm and hand becomes even more important. In addition to further exploring the use of multiple EMG signals and signal processing methods for control (53–56), alternative control inputs are being studied, including head orientation and movements (57), eye movements, and signals recorded from the brain (58). In the future, cortical signals recorded from electrodes implanted in the brain will be incorporated into neuroprosthetic systems as control sources, which may allow users to control stimulated limbs more naturally (59,60).

Advances are also being made to eliminate the external control unit and RF coil by implanting the control technology and powering the stimulator with a rechargeable battery, similar to cardiac pacemakers. In development at Case Western Reserve University is a networked neuroprosthesis, a totally implantable modular FES system that can be used for all purposes, for example, upper and lower limbs, trunk support, bladder, bowel, and diaphragm function. The networked neuroprosthesis will be upgradeable to provide additional and advanced functions by adding different components, for example, stimulator and sensor modules. The advantage of the system is that multiple applications can be implemented in a single patient without the need for multiple devices that are specially designed for single applications and are difficult to integrate or upgrade (9).

### Lower Extremity Function

Historically, there have been three objectives in the application of NMES neuroprosthetic systems to the lower extremity: (a) prevent footdrop in hemiplegia (21,61–63), (b) enable standing and transfer in paraplegia (64–67), (c) enable walking in paraplegia (68,69). Today, these three objectives continue to be the focus of several commercially available systems and FES research programs.

### Footdrop Systems

In many stroke survivors diminished ankle dorsiflexion, knee flexion, or hip flexion can result in the inability to clear the floor with the affected limb during the swing phase of gait. The purpose of footdrop systems is to produce ankle dorsiflexion and eversion during the swing phase of gait by stimulating the peroneal nerve at the appropriate time in the gait cycle. Clinical indications include footdrop that requires the patient to use compensatory strategies such as circumduction, hip hike or vaulting to clear the toes on the hemiparetic side. The patient should have sufficient balance, endurance, and motor ability to ambulate at least 30 ft with minimal assistance or better. Peroneal nerve stimulation (PNS) should dorsiflex the ankle to neutral, with balanced eversion/inversion while the patient is standing. PNS provides only limited knee control. Thus, patients who require an ankle-foot orthosis (AFO) to prevent knee flexion collapse or for severe genu recurvatum are not appropriate for PNS. Footdrop systems may also be appropriate for some individuals with incomplete SCI, traumatic brain injury, and multiple sclerosis.

There are three FDA-cleared (510(k)) commercially available surface NMES systems for preventing footdrop: the Odstock dropped-foot stimulator (ODFS by NDI Medical, Cleveland, Ohio), WalkAide (Innovative Neurotronics Inc., Austin, TX), and NESS L300 (Bioness Inc., Valencia, CA). All three systems (Fig. 72-5) use surface electrodes; the cathode is placed over the common peroneal nerve just below the head of the fibula and the return electrode is placed over the tibialis anterior. What distinguishes these systems from each other is the method by which the stimulation is made to turn on at the right time in the gait cycle and the way the components of the system are packaged. The ODFS (70), developed in Salisbury, England, uses a heel switch in the shoe of the paretic side to trigger stimulation (Fig. 72-5A). When the switch is depressed (stance phase), stimulation to dorsiflexors is off; stimulation turns on when the foot is lifted. The heel switch and electrodes connect to the stimulator with small cables. The stimulator is clipped to the waistband or carried in a pocket. WalkAide, developed at the University of Alberta, is a self-contained system worn as a cuff below the knee (Fig. 72-5B), with integrated electrodes and a built-in tilt sensor that detects step initiation and controls the timing of stimulation (71,72). The NESS L300 stimulator and electrodes (Fig. 72-5C) are also packaged as a cuff worn below the knee, but uses a wireless foot-pressure sensor to trigger stimulation appropriately to the gait cycle (73). The results of a meta-analysis of eight studies of surface PNS for hemiplegic gait showed a pooled improvement in walking speed of 38%

**A****B****C**

**FIGURE 72-5.** Footdrop systems available in the United States. **A:** ODFS. (Courtesy of NDI Medical, Cleveland, OH.) **B:** WalkAide (courtesy of Innovative Neurotronics, Austin, TX). **C:** NESS L300. (Copyright 2007 Bioness Inc., Valencia, CA.)

with PNS compared to no device (74). Single-channel surface PNS appears to be effective in enhancing the gait relative to no device and may be equivalent to an AFO (75).

Two implanted footdrop systems are commercially available in Europe, but not yet in the United States: ActiGait (Neurodan A/S, Aalborg, Denmark) and STIMuSTEP (Finetech Medical Ltd, Hertfordshire, UK). The potential advantages of implanted systems are that they do not require daily placement of electrodes, stimulation may be less painful than with surface electrodes, and convenience, cosmesis, and repeatability may be improved. Also, the implanted systems have more than one channel of stimulation, which may allow a more balanced ankle dorsiflexion. The ActiGait system, developed at the University of Aalborg in Denmark, uses a 4-channel cuff electrode surgically placed around the common peroneal nerve (76). The stimulator is implanted on the lateral aspect of the upper thigh. A wireless external heel switch sends a signal to an external controller worn at the waist, which then communicates with the implant to deliver appropriate stimulation. The STIMuSTEP system, developed at the University of

Twente in the Netherlands, consists of a 2-channel stimulator implanted below the knee, two bipolar intraneural electrodes implanted under the epineurium of the two branches of the common peroneal nerve to allow control of inversion and eversion, an external transmitter with a built-in antenna worn over the implant below the knee, and an external cabled heel switch (77). Significant improvements in walking speed have been reported with both the ActiGait and STIMuSTEP systems.

### Standing and Transfer Systems

The primary objective of some lower extremity NMES systems is to enable persons with paraplegia due to thoracic or low cervical level SCI to stand from a seated position and transfer to another surface independently. The functional goals associated with standing include reaching for high objects, having face-to-face interactions with other people, performing tasks that require standing, and transferring between surfaces (e.g., bed to wheelchair and back) independently or with only minimal assistance. The earliest demonstration of standing with NMES was achieved by stimulating the quadriceps and glutei muscles

for knee and hip extension with surface electrodes (64). Later studies showed that standing could be achieved in some subjects with stimulation of the quadriceps alone (65,66), but a more recent study suggests that adding stimulation of the hip extensors could speed up the rising phase, thereby reducing the overall effort (78). A balance aid such as a walker is still required for all NMES standing systems; voluntary control of upper extremities to maintain stability and balance is required. All NMES systems that enable walking in paraplegia also enable standing (see Walking Systems). There is one NMES system that is currently available as part of a clinical trial and that has standing and transfer as its primary aim (79).

The implanted neuroprosthesis for standing and transfer (Fig. 72-6) (79), developed at the Cleveland VA Medical Center and Case Western Reserve University, uses an 8-channel implantable stimulator (48). Epimysial electrodes are implanted bilaterally on the vastus lateralis, gluteus maximus, and semimembranosus (or alternatively, the posterior adductor magnus) for knee and hip extension, and intramuscular electrodes are implanted in the lumbar erector spinae for trunk support. The stimulator is implanted in the anterior lower abdomen (80). The user triggers stimulation with the press of a button. The button can be worn as a ring around the index finger (command ring) and activated with the thumb, or can be mounted on a walker, which is used to assist with balance. The command ring is connected with a cable to an external control unit, which is worn around the waist. The external control unit communicates with the stimulator through an RF-transmitting coil taped over the implant. When the button

on the command ring is pressed, a short delay allows the user to comfortably position their hands on an assistive device before stimulation to the trunk, hip, and knee extensors increases to a level sufficient to raise the body from the seated position and maintain continuous standing. Another press of the button reverses the process and lowers the user to a seated position in a controlled fashion.

In a pilot study of 12 subjects with C6-T9 level SCI, the strength of knee and hip extension produced with the CWRU/VA standing system was adequate to achieve standing in all subjects (79). The subjects generally maintained more than 85% of their body weight on their legs and could stand for periods ranging from 3 to 40 minutes. While standing, they were frequently able to release one hand from the balance aid and manipulate objects in the environment. Some were even able to use the system for limited swing-through gait with a walker. The neuroprosthesis also reduced the effort and assistance required to transfer, especially from a lower surface to a higher one. All of the subjects expressed satisfaction with the device and indicated that they would go through the surgery and rehabilitation again to achieve the same results (80,81). Preliminary results indicate that stimulation thresholds are stable and internal components are reliable with survival rates of epimysial electrodes in the extremities approaching 95% (26). To date, a total of 17 subjects have received the CWRU/VA standing system. Usage data for the last 30 consecutive days surveyed for each individual currently in long-term follow-up (12 to 36 months) show that some form of use was logged on 40% of the days surveyed (82).

**FIGURE 72-6.** Schematic drawing of the 8-channel implanted CWRU/VA standing system. (Courtesy of the Cleveland FES Center, Cleveland, OH.)

### Walking Systems

The ultimate objective of lower extremity FES systems is to enable individuals with complete paraplegia to walk again. Some walking systems may also be applicable to individuals with incomplete paraplegia or hemiplegia to assist gait. Pioneering work by Kralj, Bajd, and others in Ljubljana, Slovenia, introduced the technique of eliciting a flexion withdrawal reflex of the hip, knee, and ankle by stimulating the peroneal nerve (68,69). This action, elicited by a single electrode, produces lower extremity motion that can be substituted for the swing phase of gait. Stimulation of the quadriceps for knee extension during the stance phase of gait completes the gait cycle. Hence, it is conceivable to provide ambulation with just four stimulus channels and bracing at the ankles. In patients who cannot voluntarily extend the hips, the gluteal muscles are stimulated as well, for a total of six stimulus channels.

This stimulation technique gave rise to the only FDA-approved (PMA) NMES system for walking. The Parastep system (Sigmedics, Inc., Fairborn, Ohio) uses four or six channels of bilateral surface stimulation of the quadriceps, peroneal nerves (for reflex flexion withdrawal), and, if necessary, the glutei to enable individuals with T4-12 paraplegia to walk with a walker (83). A microprocessor/stimulator unit is worn at the waist, and using a walker with controls built into the handles, individuals with paraplegia can stand and walk with reciprocal gait for limited distances. Parastep has been fitted to more than 1,000 users, with nearly all of them achieving standing and at least 30 ft of ambulation (84,85). Use of the system has additional medical benefits, such as increased blood flow to the lower extremities (86), lowered heart rate at subpeak work intensities (87), increased muscle mass (88), and psychological benefits (89). However, a more recent assessment of the Parastep (90) concluded that in spite of its ease of operation and good cosmetic acceptance, the Parastep approach had limited applications for mobility in daily life because of its modest performance associated with high metabolic cost and cardiovascular strain. Other complications include poor standing posture in some due to hip flexion generated by the rectus femoris when the quadriceps are stimulated, lack of or habituation of an adequate flexion withdrawal reflex, and difficulty controlling the swing limb motion due to the mass flexion response of the reflex. In 2003, Parastep was approved for reimbursement (cost of equipment and training) through the Center for Medicare and Medicaid Services (CMS).

Percutaneous (91-93) and implanted (94,95) NMES walking systems have been tested in clinical trials. Rather than eliciting a reflex to produce stepping, these systems attempt to stimulate multiple individual muscles with appropriate intensities and timing to create walking movements in response to the user pressing switches to initiate stepping. Presently, researchers in Cleveland are extending the functionality of their standing system (see Standing and Transfer Systems) with a 16-channel system. The 16 channels are provided by either two 8-channel stimulators implanted bilaterally (95,96), or more recently, by a single 16-channel stimulator. With this approach, four individuals with paraplegia have been given the ability to stand and

walk (using a walker) with standby assistance; three of these have complete injuries. This research group has also recently reported on the use of a single 8-channel implanted system for walking in a patient with incomplete (ASIA C) SCI (97). After 12 weeks of training, with the neuroprosthetic system the participant's functional ambulation category improved from non-functional to limited community ambulation. Practice with the system over 12 weeks significantly decreased the physiological effort required to walk and increased the walking distance and speed. Since that report, a second patient with incomplete SCI has received a 12-channel system (IST12 technology) with EMG control for walking, and more studies are planned.

One major drawback of walking with NMES, regardless of the system design, is the high metabolic cost primarily due to the great mechanical work needed to support the body weight and achieve forward progression. Hybrid systems reduce the energy required for walking by combining NMES systems with mechanical orthoses (98). The bracing supports the user's body weight, and the stimulation provides propulsion. The most widely tested hybrid system is the reciprocating gait orthosis (RGO) (99), which uses surface stimulation of the quadriceps (rectus femoris) and hamstrings to help power hip flexion and extension. Although hybrid RGOs are often successful in allowing users to stand and walk with less energy consumption, they are difficult to put on and are often cosmetically unacceptable, and therefore have low long-term usage rates. Other more recent hybrid system developments include an energy storage orthosis using a pneumatic component to store energy during one phase of the gait cycle and transfer it during the other phase (100).

### Future Directions

Advances toward fully implanted footdrop systems are being made. Neurostep (being developed by Neurostream Technologies Inc., Saint-Augustin-de-Desmaures, Quebec, Canada) uses a nerve cuff electrode on the tibial nerve to record afferent signals from sensory receptors in the foot (101). A gait event detection algorithm detects heel contact and toe lift, and triggers an implanted stimulator to deliver pulses to the ankle dorsiflexors through a second 4-channel nerve cuff placed on the common peroneal nerve. An initial feasibility case study reported by Hoffer et al. demonstrated gait event detection success rates ranging from 72% to 90% (8). Clinical trials have begun in Canada and are planned for the United States. Also, the injectable microstimulator (BION) approach is under investigation for the correction of footdrop (102).

For standing and walking systems, researchers are investigating the use of implanted nerve cuff electrodes to provide more complete muscle recruitment, and thereby improve standing posture and extend standing duration (27,103). Future standing and walking systems will aim to reduce or eliminate the need for assistive devices for balance (e.g., walker, crutches, or additional bracing) by incorporating automatic control of balance (104,105). By automatically adjusting for externally applied perturbations, the user's hands will be free to perform reaching tasks or other functional activities. In addition,

automatic control of the stimulation sequence during walking would produce a more efficient and natural gait (106). New implant technology with more stimulation channels could be used to: a) activate synergistic or complementary muscles, b) activate trunk muscles for greater stability when standing or sitting, or c) achieve more complete activation of the targeted muscles. This would improve system performance, simplify surgical installation, and make implanted standing and walking neuroprostheses applicable to a wider user population.

### Respiratory Function

Following cervical SCI, a significant number of individuals suffer from chronic respiratory insufficiency because the central neural connections to the diaphragm are disrupted. The diaphragm is innervated by the phrenic nerve, which consists of nerve fibers that derive primarily from C3, C4, C5, and even C6 lower motor neuron and nerve roots, but most of its nerve supply comes from the C4 neurological segment (107). Therefore, an injury to the spinal cord above C4 level will result in respiratory failure requiring mechanical ventilatory assistance, often permanently. A mechanical respirator sustains life by continuously forcing air into and out of the lungs through a tracheostomy at the base of the neck. Unfortunately, mechanical respiration is associated with substantial morbidity, mortality, inconvenience, physical discomfort, fear of disconnection, difficulty with speech, impaired sense of smell, and encumbered mobility (108). A clinical condition that spares the lower motor neurons that innervate the diaphragm (such as a complete transverse lesion at C1 and C2 levels) may allow electrical activation of the diaphragm by stimulating the phrenic nerves. The purpose of a respiratory neuroprosthesis is to restore breathing by rhythmically activating the diaphragm by this technique, and thereby eliminate the need for a mechanical respirator.

Electrical stimulation can be used to activate the diaphragm through the phrenic nerve. This technique, known as phrenic nerve pacing, was introduced in the 1960s by Glenn and colleagues at Yale University (109). Bilateral synchronous stimulation of the phrenic nerves causes contraction and descent of each hemi-diaphragm, which subsequently causes a fall in intrathoracic pressure and inspiration. Cessation of stimulation results in relaxation of the diaphragm, an increase in intrathoracic pressure, and exhalation. The stimulation cycle is repeated 8 to 14 times per minute to produce a normal breathing pattern. The user may adjust the number of breaths per minute and the duration of each breath.

Candidates for phrenic nerve pacing must have proven viability of the phrenic nerves, must be free of significant lung disease or primary muscle disease, have good sitting tolerance, strong desire and motivation, good family support, and a clear understanding of the potential benefits to be achieved. Typically, a significant surgical procedure is required, which brings associated potential complications. Therefore, patients must be carefully screened. Phrenic nerve function is assessed with electrical stimulation of the cervical portion of the phrenic nerve and simultaneous monitoring of the diaphragmatic

responses by surface electromyography to measure conduction velocity. In addition, a fluoroscopic examination of the chest should be done to verify that there are adequate diaphragmatic excursions in response to stimulation (110).

Currently there are at least two conventional phrenic pacing systems commercially available, the Avery Mark IV Breathing Pacemaker system (Avery Biomedical Devices, Commack, NY), and the Atrostim Phrenic Nerve Stimulator (Atrotech Ltd, Tampere, Finland). Both these systems have phrenic nerve stimulating electrodes implanted bilaterally in the cervical or thoracic regions and RF receiver/stimulators implanted under the skin on the anterior chest wall with implanted leads connecting the electrodes to the stimulators (Fig. 72-7). The stimulators receive power and commands from an external control unit, transmitted via an antenna taped directly over each implanted stimulator. The differences between the systems are mainly in the type of electrodes and stimulation strategies used. The Avery system, developed by Glenn et al. (109,111), uses either monopolar or bipolar electrodes that the surgeon positions around the nerve and sutures in place. The Atrostim system uses quadripolar electrodes having four contacts spaced evenly around the phrenic nerve (112). Each of the four contacts in turn serves as the cathode, and a contact on the opposite side of the nerve serves as the anode. This multipole sequential stimulation technique is intended to reduce fatigue by activating motor units only one fourth of the activation time that occurs with conventional monopolar stimulation. The Avery system is FDA-approved (PMA), has approval for reimbursement through CMS, and is the most widely used phrenic pacing system worldwide.

**FIGURE 72-7.** Avery Breathing Pacemaker system. (Courtesy of Avery Biomedical Devices, Commack, NY.)

The Atrostim system is commercially available in Europe and has been approved for investigational use by the FDA under an Investigational Device Exemption (IDE) in the United States.

Surgical implantation of phrenic pacing systems may be done by a cervical or thoracic approach (111,113). The thoracic approach requires a thoracotomy to expose the phrenic nerve, which has significant associated risks including hemothorax and pneumothorax, and which requires chest tube placement and intensive postoperative care. Alternatively, the stimulators and electrodes may be implanted without a thoracotomy through an incision in the neck, but with this approach submaximal diaphragm activation may result because additional accessory branches join the phrenic nerve in the thorax in most individuals. The thoracic approach, therefore, has been the preferred method of electrode placement (114). More recently, an endoscopic technique has been developed to allow the electrodes to be implanted without a thoracotomy (115). Although there are a number of acceptable surgical approaches for thoracic electrode placement, the phrenic nerves are usually accessed by incisions through the second intercostal spaces and the electrodes are secured behind or over the nerve. It is critical that the phrenic nerves are manipulated with extreme care to avoid mechanical trauma to the nerve and its blood supply. The stimulator is positioned in a subcutaneous pocket on the anterior chest wall; leads from the electrode are passed through the third or fourth intercostal space and connected to the stimulator.

Postoperatively, the diaphragm is gradually reconditioned to reverse disuse atrophy and to regain strength and endurance (116). Conditioning is initiated approximately 2 weeks after surgery. Phrenic nerve pacing is initially done daily for 10 to 15 minutes every hour and is gradually increased over a conditioning phase that may take 10 to 12 weeks or longer, although it is possible to achieve full-time pacing in some patients within 5 weeks (108). Low-frequency stimulation is used during the conditioning phase to promote conversion of fast-twitch fibers to slow-twitch fatigue-resistant fibers. After pacing is achieved throughout the waking hours, pacing is done during sleep and gradually increased until the pacer is used full time. Generally, the tracheostomy is kept open, but it may be capped especially during waking hours. By leaving it open, suctioning and removal of secretions is made easier and mechanical ventilation may be restarted when medically necessary. During sleep, the tracheostomy should be open in order to reduce the risk of upper airway collapse and obstructive apnea.

Phrenic nerve pacing has allowed patients to decrease or even discontinue the use of mechanical respirators and have enabled more normal breathing. Although there may be significant patient variability, most patients describe an improved level of comfort, reduced anxiety and embarrassment, increased mobility, improved speech, and greater sense of well being and an overall health as most important benefits as compared to mechanical ventilation (117–119). While a number of complications have been reported since phrenic nerve pacing was first introduced,

technical developments and patient experience have markedly reduced their incidence (118,120). Early failures were mainly due to technical malfunction of the device components or due to insufficient phrenic nerve innervation (a patient selection error). Additional complications encountered include diaphragm fatigue, increases in airway resistance caused by the accumulation of airway secretions (requires suctioning), infection, injury to the phrenic nerve, and upper airway obstruction after tracheostomy closure (108).

There are only a few studies that have evaluated recent success and complication rates. In one long-term follow-up study of 12 quadriplegic patients, 50% continued to use the Avery system full time (mean 13.7 years), one used it part time, three stopped using it, and two were deceased (one had used the system full time, and one had stopped using it) (121). Those who stopped using the pacer did so because of inadequate social or financial support or medical problems associated with the initial injury. All patients demonstrated normal tidal volumes while pacing full time, no patient lost the ability to activate the phrenic nerve, and threshold and maximal currents did not increase over time. In an international study of 64 patients using the Atrostim system, 94% of the 35 pediatric patients and 86% of the 29 adult patients eventually achieved complication-free successful pacing (122). Thirty-four percent of all subjects paced full time, 38% paced only while awake, 14% paced only while asleep, and 2% stopped pacing. The incidences of electrode and stimulator failure were 3.1% and 5.9%, respectively, and the incidences of infection and nerve trauma were 2.9% and 3.8%, respectively.

Alternative electrode placement procedures have been developed to reduce surgical risks and associated costs. One such alternative uses a minimally invasive laparoscopic procedure to position intramuscular electrodes bilaterally near the motor points of each hemi-diaphragm (123,124). With this procedure, four laparoscopic ports provide access to the abdominal cavity for visualization, insufflation of the abdominal cavity, diaphragm mapping, and insertion of the implant tool and four electrodes (124,125). The electrode leads are tunneled subcutaneously to the chest wall where they exit and connect to an external stimulator. This percutaneous diaphragm pacing system is called NeuRx DPS system (Synapse Biomedical, Inc., Oberlin, Ohio); it has recently received FDA approval (PMA) and also has the CE Mark for marketing in Europe. The system has been implemented in at least 55 patients with SCI, with over 90% achieving significant independence from mechanical ventilation and over 50% eliminating mechanical ventilation. Initial experience with the first five patients has been reported (123). The system has also been implemented in at least 70 patients with ALS under an IDE, with preliminary results indicating an improvement in the rate of respiratory decline, improvements in sleep disordered breathing, apparent trophic effects as demonstrated by increasing EMG activity of the diaphragm with conditioning, improvements in respiratory system compliance, and improved survival (mean survival from diagnosis appears to be 61 months for DPS patients).

### Future Directions

Unfortunately, many individuals with ventilator-dependent tetraplegia are not eligible for phrenic nerve pacing because of complete or partial injury of one of the phrenic nerves. For patients with only a single functional phrenic nerve, it may be possible to achieve respiration by activating the inspiratory intercostal muscles in addition to the functioning phrenic nerve (126,127). In a study of four patients with SCI between C2 and C4 levels, upper thoracic epidural spinal cord stimulation of the intercostal muscles, in combination with phrenic nerve stimulation, produced inspiratory volumes equal to that typically achieved with bilateral phrenic nerve pacing (127,128). However, intercostal pacing also results in contraction of nonventilatory muscles and therefore is less efficient than diaphragm pacing. Nevertheless, the patients in this study were able to achieve substantial time free of mechanical ventilatory support, and all four reported a level of comfort very near normal breathing. This approach continues to be developed. For patients with significant injury to both phrenic nerves, the development of an intercostal to phrenic nerve transfer procedure (129) may restore phrenic nerve viability and allow these patients the possibility of diaphragm pacing.

Additional avenues of research and development include the use of computer-aided robotic technology to implant electrodes around the phrenic nerves through three 1-cm incisions in the intercostal spaces on each side (130), thereby avoiding the conventional and invasive thoracotomy procedure. Others are working on developing a totally implanted system similar to cardiac pacemakers. Researchers in Japan have used a Medtronic spinal cord stimulator (Itrel 3), an implant with its own battery and requiring no RF communication or external components (except for programming), as a diaphragm pacer in six patients with encouraging results (131,132). Systems are also being developed to produce cough and thereby reduce the risk of developing respiratory tract infections as the result of expiratory muscle paralysis (133–135). Recently, a new method has been tested to activate the expiratory muscles via lower thoracic and upper lumbar spinal cord stimulation (136).

### Bladder and Bowel Function

SCI above the sacral levels of the spinal cord results in loss of bladder and bowel control. Numerous complications related to this loss of function include frequent urinary tract infections, renal deterioration, bladder or kidney stones, and autonomic dysreflexia. These complications threaten to compromise the health and quality of life of the individual, and can lead to major long-term, and even deadly, consequences. The functional goal of a bladder neuroprosthesis is to produce effective micturition (bladder voiding) and continence, and also improve bowel function.

Micturition and continence are normally performed by the coordinated action of the bladder (detrusor muscle) and the urethral sphincter, two muscles that are controlled by neural circuits in the brain and lumbosacral spinal cord. Micturition normally occurs when the bladder contracts while

the urethral sphincter relaxes; continence normally occurs when the bladder relaxes while the urethral sphincter contracts. Suprasacral SCI disrupts the coordination and control of the two muscles, resulting in detrusor-sphincter dyssynergia and neurogenic detrusor overactivity (also called detrusor hyperreflexia). Detrusor-sphincter dyssynergia is a condition when the bladder and urethral sphincter contract simultaneously rather than reciprocally, thereby impairing micturition. Neurogenic detrusor overactivity is characterized by involuntary detrusor contractions during the filling phase, thereby impairing continence. These effects result in elevated bladder pressure, which is the primary risk factor for renal deterioration. Thus, a reduction of bladder pressure is also an important objective of a neuroprosthesis for bladder function.

The use of electrical stimulation for restoring bladder control has been most advanced in the United Kingdom by the work of Giles Brindley (137). The Finetech Brindley Bladder Control system (Finetech Medical, Ltd, Hertfordshire, UK) is an implanted FES system that enables micturition by producing a bladder contraction with stimulation of the sacral anterior spinal nerve roots. The system has been implanted in more than 2,500 patients in at least 20 countries (138,139). The system is FDA-approved (PMA) in the United States and has the CE mark in Europe. The majority of the first 500 patients had SCI; however, patients with other neurological disorders, including multiple sclerosis, spinal cord tumors, transverse myelitis, cerebral palsy, and meningomyelocele have also received the implant (140). Candidates must have intact parasympathetic neurons to the detrusor muscle. The function of these neurons is demonstrated by reflex detrusor contractions on a cystometrogram. Frequent urinary tract infection and problems tolerating catheters or anticholinergic medication are further indications. Patients can receive an implant at any time after reaching neurological stability. They should also have an appropriate degree of emotional and social stability.

The system consists of two pairs of tripolar electrodes (active contact flanked on each side with a return contact), an implanted receiver/stimulator and an external control unit that powers and controls the stimulator through an RF transmission antenna (Fig. 72-8). The electrodes are implanted bilaterally on the sacral spinal nerve roots either intradurally on the anterior (motor) roots in the cauda equine via a lower lumbar laminectomy (141), or extradurally on the mixed sacral nerves in the sacral canal via a laminectomy of S1-3 (142). The advantage of the intradural approach is that it attempts to only activate efferent fibers and therefore minimize activation of reflexes through the posterior sacral roots. However, the extradural approach is reported to carry less risk of trauma to the nerves or of cerebrospinal fluid leakage. Intraoperative electrical stimulation and recording of bladder pressure is used to confirm the identity of the nerves supplying the bladder. The electrode leads are tunneled to the receiver/stimulator, which is placed under the skin on the anterior abdominal wall through a separate incision. Bilateral posterior rhizotomies of the S2-4 spinal nerves are usually performed to eliminate involuntary detrusor contractions (associated with neurogenic detrusor

**FIGURE 72-8.** FineTech Brindley Bladder Control system. (Courtesy of FineTech Medical, Ltd, Hertfordshire, UK.)

overactivity) and thereby provide continence. Postoperatively, urodynamic studies are used to guide the setting of stimulus parameters to give an acceptable voiding pressure and rate and pattern of flow. The stimulus program is checked between 1 and 3 months after surgery since the response of the bladder may change with repeated use; thereafter, review is recommended at least annually, monitoring lower and upper urinary tract function. The external control unit has programs for bladder or bowel control, which the user selects and then turns the device on to deliver the appropriate pattern of stimulation to the sacral nerves.

Stimulation of the sacral nerve roots not only results in contraction of the detrusor, but also of the external urethral sphincter, an effect that does not seem conducive to micturition. This coactivation occurs because the sacral nerve roots contain both the small-diameter preganglionic parasympathetic axons innervating the bladder via the pelvic nerve and the large-diameter somatic motor axons innervating the external urethral sphincter through the pudendal nerve. Because the large fibers have a lower threshold for excitation than smaller fibers, it is difficult to produce contraction of the detrusor without contraction of the external sphincter. Nevertheless, micturition can be produced by intermittent stimulation, a technique that takes advantage of the fact that the relaxation time of the smooth detrusor muscle is longer than that of the striated external urethral sphincter muscle. Intermittent

stimulation (3 to 6 seconds on, 6 to 9 seconds off) leads to sustained contraction of the bladder and relaxation of the sphincter between stimulus periods. Thus, urine flows during the intervals between stimulus periods and the bladder is emptied in spurts, an effect called poststimulus voiding.

A multicenter study has reported that more than 85% of 184 implant recipients use the system as the primary means of bladder emptying (139). Residual volume in the bladder following system use was less than 60 mL in 95% of the users and less than 30 mL in 89%. A substantial decrease in symptomatic urinary tract infections following use of the implant has been reported in several studies (139,143–145). Continence is reported in more than 85% of patients (139,140,145,146), largely because of increased bladder compliance following the posterior rhizotomy (147,148). About 10% to 15% of patients report some stress incontinence of urine following implantation of the stimulator and posterior rhizotomy (147). Several centers in Europe have long-term follow-up experience with the device, particularly with regard to the upper tracts (139,146,149,150). Trabeculation, ureteric reflux, and hydronephrosis tend to decrease in patients who undergo implantation and posterior rhizotomy. There is also a reduction in the incidence of autonomic dysreflexia, an outcome that is particularly beneficial to males with tetraplegia who were formerly dependent on an indwelling catheter, which is prone to blockage and frequent infection. The ability to micturate on demand and improved continence of urine contribute to a reduction in the use of intermittent and indwelling catheterization. Most users become free of catheters and urine collection bags and can discontinue anticholinergic medication, which in turn reduces constipation and other side effects such as dry mouth and drowsiness (143,151). Satisfaction with the system has been reported to be high (143), and the hardware has been reliable (152). Infection associated with the implant is rare, occurring in 1% of the first 500 implants and technical faults in the implanted equipment is uncommon, occurring on an average once every 20 implant-years (152). Studies in Europe and the USA indicate that the use of the implanted stimulator together with posterior sacral rhizotomy results in substantial savings in the cost of bladder and bowel care, particularly from reduction in supplies needed for bladder care, medications, and visits to physicians for the management of complications (153–155).

Bowel evacuation and penile erection are secondary uses of the Finetech Brindley Bladder system. Regular stimulation of the sacral parasympathetic nerves contributes to the transport of stool through the distal colon into the rectum (156). Most users report a reduction in constipation and reduced need for laxatives and stool softeners (156,157). Some users are able to defecate by a pattern of intermittent stimulation similar to that used for micturition but with longer intervals between bursts of stimulation to allow passage of stool (157). This results in a significant reduction in time that is spent in bowel evacuation (143,157). Penile erection has been reported in 60% to 87% of men with intradural electrodes implanted on the anterior sacral roots (140,145,146). In a smaller group

of participants with extradural sacral root stimulation, penile erection by stimulation was achieved in only approximately 10% (151).

### Future Directions

Methods to induce bladder contractions without activating the external urethral sphincter, and thereby achieve a more physiological voiding pattern, are being investigated (158). For example, recent animal studies show that selective stimulation of the small fibers innervating the bladder may be possible by blocking the action potentials in the large pudendal nerve fibers, innervating the sphincter with biphasic quasitrapezoidal stimulation pulses (159,160) or high-frequency sinusoidal stimulation (161,162). An alternative method for achieving selective stimulation of the detrusor without the external urethral sphincter is to induce a reflex bladder contraction without a reflex sphincter contraction by intermittent stimulation of the pudendal nerve trunk (163).

Researchers are also exploring alternatives to posterior sacral rhizotomy for reducing neurogenic detrusor overactivity. While the benefits of posterior rhizotomy are clear—abolition of reflex incontinence, increased bladder capacity and compliance, prevention of autonomic dysreflexia triggered from the bladder or bowel, and protection of the kidneys from ureteric reflux and hydronephrosis (143)—posterior rhizotomy also abolishes other potential useful sacral reflexes, such as reflex erection, ejaculation, defecation, and sacral sensation if present. One alternative to posterior rhizotomy is to induce reflex inhibition of the detrusor by electrically stimulating large afferent neurons in the sacral dermatomes, a technique known as neuromodulation, which shows some benefit in able-bodied subjects with urge incontinence (164,165). Similar inhibition has been observed following SCI using the Finetech Brindley system without posterior rhizotomy but with stimulation of the posterior sacral afferents to suppress bladder overactivity (166). With this system, neuromodulation increased bladder capacity, but hyperreflexia of the external urethral sphincter persisted and prevented complete emptying in some cases. Another approach is to mimic the function of a posterior rhizotomy only when needed by blocking the action potentials in the posterior sacral afferents with a high frequency electrical stimulation neural block that is fast-acting and reversible (167,168). Although this approach is still at the level of animal experimentation, its clinical implications reach far beyond the bladder application and may include management of the broader problems of spasticity and pain.

## CONCLUSIONS

The principal goal of rehabilitation management of persons with upper motor neuron paralysis is to maximize the quality of life. While quality of life is clearly influenced by a wide range of variables including social, emotional, psychological, vocational, and educational factors, the persistent

neurological impairment after injury to the central motor system remains a powerful reminder and determinant of one's ability to function in society. Functional NMES systems bypass the injured central circuitry to activate neural tissue and contract muscles to provide function to what is otherwise a nonfunctioning limb or organ. Recent advances in clinical medicine and biomedical engineering have made the clinical implementation of functional NMES systems to enhance the mobility and function of the paralyzed person more feasible. Hand neuroprosthesis systems can significantly enhance the upper extremity ADL of persons with tetraplegia. The application of this technology for persons with hemiplegia is in its infancy and must await further technical and scientific developments if it is to be applicable to the broader stroke population. Recently, several footdrop systems for hemiplegia have reached the commercialization stage. Several lower extremity systems with and without bracing are being investigated for the purpose of functional transfers and standing, and for ambulation for patients with paraplegia. Phrenic pacing systems can provide artificial ventilatory support for patients with ventilator-dependent SCI. Finally, the bladder neuroprosthesis can provide catheter-free micturition for persons with either paraplegia or tetraplegia.

For more than 40 years, electrical stimulation has been used to restore neuromuscular function in people with paralysis. The principles of safe and reliable activation of neural tissue and the methods of generating stable and controllable muscle contractions have been well established. Electrodes, stimulators, transducers, and sensors have been developed and integrated into neuroprosthetic systems that have benefited individuals with SCI and stroke. Clinical success of several FES interventions has been demonstrated, but commercial success has proven to be more difficult to achieve, especially for upper and lower extremity implanted systems. Expanding the indications both within the SCI and stroke populations, and beyond those populations to other disability groups, will increase the number of people benefited and the potential market size. Increasing the awareness of FES technology and its benefits among rehabilitation practitioners and involving them in the development and clinical testing of neuroprostheses are important components in increasing the number of FES users and in penetrating the market. Costs can be decreased by developing systems that can be more easily manufactured and implemented. Technological advancements will increase the benefit of neuroprostheses, leading to greater function and independence for neurologically impaired individuals.

# Assistive Technology

## HISTORICAL BACKGROUND AND PERSPECTIVE ON ASSISTIVE TECHNOLOGY

Humans have used tools to accomplish everyday tasks in many cultures throughout history (and prehistory), but the perception remains that the use of technology as a tool for persons with disabilities is a fairly recent phenomenon. In fact, James and Thorpe describe any number of assistive devices used as early as the 6th or 7th century B.C. (1). Their descriptions include partial dentures, artificial legs and hands, and drinking tubes or straws. The earliest documented account of optical and lens technologies, or eyeglasses, came from Venice around A.D. 1300 (2). The term *assistive technology* (AT) to describe devices used to facilitate the accomplishment of everyday tasks by persons with disabilities is actually the more recent development (3).

In 1988, Public law 100-407 defined AT as “Any item, piece of equipment or product system whether acquired commercially off the shelf, modified, or customized that is used to increase or improve functional capabilities of individuals with disabilities.” This definition also included a second component defining AT services as any service that directly assists an individual with a disability in the selection, acquisition, or use of an AT device. This includes

1. The evaluation of the needs of an individual with a disability, including a functional evaluation of the individual in his or her customary environment;
2. Purchasing, leasing, or otherwise providing for the acquisition of AT by persons with disabilities;
3. Selecting, designing, fitting, customizing, adapting, applying, retaining, repairing, or replacing AT devices;
4. Coordinating and using other therapies, interventions, or services with AT devices, such as those associated with existing education and rehabilitation plans and programs;
5. Training or technical assistance for the person with a disability or, if appropriate, his or her family;
6. Training or technical assistance for professionals (including individuals providing education or rehabilitation services), employers, or other individuals who provide services to, employ, or are otherwise substantially involved in the major life functions of children with disabilities (4).

This definition has also been included in other federal legislation authorizing services or supports for persons with

disabilities, including the Rehabilitation Act (5) and the Individuals with Disabilities Act (6).

So what is AT? In short, AT is *a tool* used by someone with a disability to perform everyday tasks such as getting dressed, moving around, or controlling his or her environment, learning, working, or engaging in recreational activities. As a tool, AT is no different than using a hammer to drive a nail. Fewer than 30 years ago, there were fewer than 100 devices commercially available. Today, more than 29,000 assistive devices are listed on the AbleData Web site ([www.abledata.com](http://www.abledata.com)). AT use often begins shortly after birth and continues throughout the life span of individuals with disabilities.

Included within this textbook are chapters on wheelchairs and other mobility aids, recreational therapies, orthotics and prosthetics, and many other rehabilitation devices or tools. The devices described by the authors of these chapters also fall within the definition of AT. This chapter covers basic information on various categories of AT products, evaluation, prescription and funding for AT, use of a team approach, and outcomes measurement in the field of AT devices and services. Readers are referred to the appropriate chapter for more in-depth information on those devices covered elsewhere in the textbook.

AT tends to be divided into two major categories: low technology and high technology. Low-technology or “low-tech” devices tend to be simple, nonelectronic devices. Items such as dressing aids, pencil grips, picture-based communication boards for persons who are nonspeaking, and magnifiers for persons with visual impairments fall within the category of low-tech devices. High-technology or “high-tech” devices are typically described as sophisticated, electronic devices such as power wheelchairs, computers, or augmentative and alternative communication (AAC) devices that provide voice output for persons who are nonspeaking. These devices are usually fairly expensive and often require extensive training to ensure they are used to their fullest potential (7).

There are a number of myths surrounding the provision of AT that tend to reflect common misperceptions about both the technology and individuals with disabilities. These myths include

1. AT is the “be all and end all.”
2. AT is complicated and expensive.
3. Persons with the same disability benefit from the same devices.

4. Professionals are the best source of information for AT.
5. AT descriptions are always accurate and helpful.
6. A user's AT requirements need to be assessed just once.
7. AT devices will always be used.
8. Individuals with disabilities want the latest, most expensive device.
9. AT is a luxury.
10. Only people with certain types of disabilities find AT useful.

Although AT does hold a great deal of promise for persons with disabilities who would like to pursue everyday tasks that most of us take for granted, myths such as these have a tendency to cause practitioners and those they serve to disregard the potential utility of assistive devices. Tasks such as navigating freely throughout the community, talking with a loved one, and writing a letter are often out of reach for persons with disabilities. Proper prescription of assistive technologies can enable persons with disabilities to learn, work, and play, just like everyone else. Dispelling these myths can do much to ensure that those who can benefit from assistive devices and services receive appropriate supports.

## AT AND ABANDONMENT

It is important to recognize that not everyone with a disability enjoys using technology, however useful it might appear to practitioners. Depending on the type of technology, nonuse or abandonment can be as low as 8% or as high as 75%. On average, one third of more *optional* ATs are abandoned, most within the first 3 months after acquiring the device. To date, research has not been done to ascertain the number of individuals who must continue to use devices they are not pleased with simply because they cannot abandon the technology without severe consequences (8,9). For example, an individual who has just received a new wheelchair that does not meet expectations simply cannot stop using the chair to navigate independently within his or her community. Rather, he or she must wait until third-party funding becomes available again (often as long as 3 to 6 years) or engage in potentially difficult and unproductive discussions with the vendor who has more than likely provided the chair as it was prescribed by the assessment team.

Research does tell us the number one reason individuals with disabilities choose not to use assistive devices is because practitioners failed to consider their opinions and preferences during the device selection process. In other words, the person with a disability was not included as an active member of the team during the evaluation process (8).

## HUMAN FACTORS AND AT

A growing body of research in the field of human factors is being applied to the design and development of AT devices

for persons with disabilities. Analysis of human factors in a global sense is concerned with how humans interact with various technologies. When you sit in a new car and notice how comfortable it is—how well the seat contours with your body and how accessible the controls are for the stereo system—you have experienced the growing information derived from human factors research.

Dr. King (10), a professor at the University of Wisconsin-Eau Claire, has expanded key points found in the literature on human factors and applied them to research and development in AT. He tells us that human factors in AT must be concerned with how human beings who have special needs, limitations, or disabilities interact with devices and tools that may support, supplement, or replace some process or ability that has been lost or impaired by illness or injury. We must be concerned not only with how the user interacts with the devices but also with how the family or other close care providers react to the use of tools and devices in their settings. The interaction of the AT user alone with the technology does not tell us the whole story because persons who use assistive technologies must interact closely and frequently with, or depend on others, for daily care and other aspects of their lives. The larger impact on those around the user must also be considered because they are key players in the implementation of any AT in the user's life. Across all component areas of AT, human factors must be concerned with how the potential user—as well as his or her family, personal care providers, education and therapy aides, teachers, and clinicians—interacts with the assistive devices and technological systems.

Analysis of human factors in AT is concerned with finding out the special needs, capabilities, and limitations of users and then matching devices and controls to each individual user. Heterogeneity and individualization are primary considerations in dealing with persons who have special needs. However, mass-produced technologies (such as computers) must be designed for mass-market users, rather than for unique individuals. Flexibility and adaptability of technology to a wide range of user characteristics are critically important.

Human factors considerations in AT are especially focused on reducing the user's exertion, stress, and fear of use. We all have a bit of "technophobia" when it comes to use of new tools and devices—especially complex, high-tech devices. The fear and stress, particularly when they relate to devices that may be difficult to set up or require a great deal of exertion to use, can be deleterious to the AT user. Persons relying on AT have some type of limitation or disability. Expecting an individual with a disability to become skilled in additional tools, devices, or technology can be highly stressful to users as well as caregivers because it adds more complexity to their life.

Human factors also focus on reducing the danger caused by the device to the user and persons around them. AT professionals should also strive to reduce the possibility of failure during use, which can lead to rejection or abandonment of the device for future use, even when the system has considerable merit for the person with a disability (10).

## AT AND THE INTERNATIONAL CLASSIFICATION OF FUNCTIONING, DISABILITY, AND HEALTH

Disability itself is not precise and quantifiable. The concept of disability is not always agreed on by persons who self-identify as having a disability, persons who study disability, or the general public (11). This lack of agreement creates obstacles for studies focused on disability and to the equitable and effective administration of programs and policies intended for persons with disabilities. To facilitate agreement about the concept of disability, the World Health Organization (WHO) has developed a global common health language—one that is understood to include physical, mental, and social well-being. The WHO first published the International Classification of Impairment, Disabilities, and Handicaps (ICIDH) in 1980 as a tool for classification of the “consequences of disease.”

The newest version, International Classification of Functioning, Disability and Health, known as ICF (2001), moves away from a “consequences of diseases” classification (1980 version) to a “components of health” classification. This latest model is designed to provide a common framework and language for the description of health domains and health-related domains. Using the common language of the ICF can help health care professionals to communicate the need for health care and related services, such as the provision of AT for persons with disabilities (12).

In the context of health, the following language is used:

- *Body functions* are the physiologic and psychological functions of body systems.
- *Body structures* are anatomic parts of the body, such as organs, limbs, and their components.
- *Impairments* are problems in body function or structure, such as significant deviation or loss.
- *Activity* is the execution of a task or action by an individual.
- *Participation* is involvement in a life situation.
- *Activity limitations* are difficulties an individual may have in executing activities.
- *Participation restrictions* are problems an individual may experience in involvement in life situations.
- *Environmental factors* make up the physical, social, and attitudinal environments in which people live and conduct their lives (12).

Application of the WHO global common health language makes possible the definition of the need for health care and related services; defines health outcomes in terms of body, person, and social functioning; provides a common framework for research, clinical work, and social policy; ensures the cost-effective provision and management of health care and related services; and characterizes physical, mental, social, economic, or environmental interventions that will improve lives and levels of functioning. Provision of AT for persons with disabilities is an intervention that has the potential to diminish activity limitations and participation restrictions and in turn, improve

the quality of life of individuals with disabilities. Throughout this chapter, the use of the WHO common health language is used to discuss the potential impact of AT.

## AT FOR MOBILITY IMPAIRMENTS

Individuals with mobility impairments often present with unique needs and abilities. Some may demonstrate only lower-body impairment, such as a spinal cord injury or spina bifida, with no other complications. AT solutions might include crutches, a scooter, or a wheelchair. Simple modifications or adaptations to the environment, such as removing physical barriers to access (wide doorway or a ramp instead of stairs), may be all that is needed. For others, automobile hand controls, adapted saddles for horseback riding, sit skis for downhill skiing, or even placing bricks under a desk or table to allow the wheelchair user to work comfortably at a workstation may be necessary accommodations.

Other adaptive equipment for persons with mobility impairments might include a van with an attached lift. Many individuals who use wheelchairs drive a wide range of motor vehicles as well as bicycles using specially customized hand controls for turning and braking (Fig. 73-1). Chapter 78, Wheelchairs, and Chapter 76, Lower Extremity Orthotics, Shoes and Gait Aids, provide in-depth discussions of a wide range of assistive technologies for persons with mobility impairments that interfere with ambulation and other activities of daily living (ADLs).

For someone with upper-body mobility impairment, such as poor hand control or paralysis, assistive devices might include alternate keyboards or other input methods to access a computer. Alternate keyboards come in many shapes and sizes. There are expanded keyboards, such as the Intellikeys (Fig. 73-2), which provides a larger surface area than a standard keyboard, larger letters with a contrasting yellow background, and options such as a delayed response of the activated

**FIGURE 73-1.** AT for mobility impairments. (Courtesy of Marlin Cohrs, Assistive Technology Partners, Department of Rehabilitation Medicine, University of Colorado Health Sciences Center.)

**FIGURE 73-2.** Intellikeys keyboard. (Courtesy of Jim Sandstrum, Assistive Technology Partners, Department of Rehabilitation Medicine, University of Colorado Health Sciences Center.)

key for individuals who have difficulty either initiating touch or removing their finger after they have activated the key. For individuals who have never used a standard QWERTY keyboard layout, letters on the keyboard can be arranged alphabetically. This key arrangement is often helpful for young children who are developing literacy skills, as well as for adults who have cognitive or visual impairments that necessitate additional supports for reading and writing.

There are also small keyboards, such as the Tash Mini Keyboard (Fig. 73-3), that are designed in what is called a “frequency of occurrence” layout. Individuals who are one-handed typists, or who use a head stick or mouth stick to type, frequently prefer a smaller-sized keyboard. The home row (middle row) consists of the most frequently occurring letters in the

**FIGURE 73-3.** Tash Mini keyboard. (Courtesy of Marlin Cohrs, Assistive Technology Partners, Department of Rehabilitation Medicine, University of Colorado Health Sciences Center.)

English alphabet, with the letters a, e, and the space bar placed in the center of the keyboard for easy access. Characters, numbers, and functions (including mouse control) keys fan out from the center of the keyboard depending on how frequently they are used by the average typist.

For individuals who are unable to use any type of keyboard or other device that requires hand mobility or finger pointing, there are a wide range of switches available that provide access not only to the computer but also to battery-operated electric toys and home-based or work appliances. These switches may be as simple as a “rocking lever” switch (Fig. 73-4) designed to be activated through a gross motor movement that involves touching or hitting the switch with the head, hand, arm, leg, or knee. Other switches can be activated by tongue touch, sipping and puffing on a straw, or through very fine movements, such as an eye blink or a single muscle twitch.

Fairly recent developments include eye gaze switches that calibrate intentional eye movement patterns and select targets such as individual keys on an on-screen keyboard, and also brain wave technology (Eye and Muscle Operated Switch or EMOS) that responds to the excitation of alpha waves to trigger the selection. Other input methods for the computer include devices such as the Head Mouse and Tracker 2000. These devices also rely on an on-screen keyboard visible on the computer monitor. The user wears a reflective dot on his or her forehead or other head-mounted signaling device to tell the computer what key or command he or she wishes to activate. With these and many other high-tech control devices, individuals with disabilities, even those with the most severe motor impairments, can monitor and control an unlimited array of home, work, and school activities.

There are thousands of lower-tech assistive devices available for persons with motor impairments. Commonly referred to as aids for daily living, these devices include such things as weighted spoons, scoop plates, and other devices used to

**FIGURE 73-4.** Switches. (Courtesy of Marlin Cohrs, Assistive Technology Partners, Department of Rehabilitation Medicine, University of Colorado Health Sciences Center.)

**FIGURE 73-5.** Aids for daily living. (Courtesy of Marlin Cohrs, Assistive Technology Partners, Department of Rehabilitation Medicine, University of Colorado Health Sciences Center.)

facilitate eating (Fig. 73-5); aids for personal hygiene, such as bath chairs and long-handled hairbrushes; adapted toys for play; built-up pencil grips for writing and drawing tasks; items for dressing, such as sock aids and one-handed buttoners; and many others. Prices and availability cover a wide range for items such as these. Many low-tech mobility aids can be handmade for just a few dollars, whereas others, such as an adult bath chair, may cost several hundred dollars. All share the common goal or utility of reducing activity limitations and increasing participation in daily life activities.

## AT FOR COMMUNICATION DISORDERS

For individuals with severe expressive communication impairments, there is a wide range of AT devices available. For persons who have reduced phonation or breath support and speak very quietly, there are a number of portable amplification systems available that work much like a sound system in a large lecture hall. There is also a device available that clarifies speech for individuals with dysarthria. Called the Speech Enhancer, it consists of a headset attached to a portable device and is worn much like a shoulder bag (Fig. 73-6). The individual using this system speaks into the microphone, and the sound is processed and then projected by speakers attached to the unit. Although not for everyone, this device has proven effective for a number of individuals struggling to be understood when communicating with medical personnel, family members, and others in the community.

For individuals who are unable to talk at all or who have such severe expressive communication difficulties that only their most intimate associates understand them, there are a wide range of AAC systems available. These devices range from very simple picture books to high-end sophisticated electronic communication devices with digitally recorded or synthetic speech output. Children and adults with severe expressive

**FIGURE 73-6.** Speech enhancer. (Courtesy of Marlin Cohrs, Assistive Technology Partners, Department of Rehabilitation Medicine, University of Colorado Health Sciences Center.)

communication impairments can benefit academically, vocationally, emotionally, and socially from the provision of a device that allows them to communicate their thoughts, learn and share information and ideas, and otherwise participate in life activities.

It is important to note these AAC devices, although extremely useful and important to the lifestyles of many individuals who are nonspeaking, do not replace natural speech. Instead they *augment* or provide an *alternate* form of communication. Other communicative modalities, such as vocalizations, gestures, sign language systems, eye gaze, etc., remain valid and acceptable forms of communication and should be encouraged to develop along with the facility to communicate out loud using an AAC device.

Congenital conditions such as autism, cerebral palsy, mental retardation, developmental verbal apraxia, and developmental language disorders can result in severe expressive communication impairments, necessitating the need for AAC interventions (13). Acquired disorders for which AAC is often used include traumatic brain injury, stroke, amyotrophic lateral sclerosis (ALS), tetraplegia, multiple sclerosis (MS), and laryngectomy that is due to cancer (7,14). Augmentative communication systems (Fig. 73-7) have also been used successfully for individuals who are temporarily nonspeaking as a result of ventilator dependence (15).

There are two common myths surrounding the use of AAC. The first is that individuals who are nonspeaking must demonstrate certain developmental prerequisites before the

**FIGURE 73-7.** Using an AAC device. (Courtesy of Jim Sandstrum, Assistive Technology Partners, Department of Rehabilitation Medicine, University of Colorado Health Sciences Center.)

prescription of an AAC device. On the contrary, there are no strict sets of cognitive or physical prerequisites to the use of AAC devices. Specific AAC techniques that match the individual's needs and abilities are chosen on the basis of a comprehensive evaluation by a qualified team of clinicians, family members, teachers, and others. The second myth is that the use of an AAC device will stifle or preclude the development or return of natural speech. However, the research tells us that use of an AAC device can actually support improved speech production and it in no way creates barriers to the development or return of natural speech (16).

Low-tech picture and alphabet boards are often used as either a preliminary step before purchasing an electronic voice output system, or as backup systems, should an electronic device break or its use not be convenient (e.g., during swim lessons). These low-tech systems (Fig. 73-8) can be made from picture library software available through commercial vendors (BoardMaker, PCS Symbols) or can be handmade using digital photographs, pictures from catalogs or books, or by simply using a marker to write or draw letters, words, phrases, or pictures. Adults with progressive diseases such as ALS or MS frequently use low-tech picture or alphabet boards to clarify their meaning as communication abilities decrease or as they fatigue during the day.

**FIGURE 73-8.** Low-tech AAC device. (Courtesy of Marlin Cohrs, Assistive Technology Partners, Department of Rehabilitation Medicine, University of Colorado Health Sciences Center.)

There are a number of low-tech voice output AAC devices available that are simple to program and use. The Talking Symbol Notepad, GoTalk, and TechTalk8 communication devices all use digital speech output (Fig. 73-9). Digital speech devices work much like a tape recorder. The person

**FIGURE 73-9.** Using the Big Mac. (Courtesy of Diane Brians, Assistive Technology Partners, Department of Rehabilitation Medicine, University of Colorado Health Sciences Center.)

setting up the device simply holds down a button and records live voice into the microphone. The speech is digitized or recorded within the device. When the end user chooses to speak, he or she simply presses to activate the device. It then speaks the prerecorded message. The good news is these devices are simple and fairly inexpensive to purchase. It is important to bear in mind, however, that they are intentionally designed to communicate quick, simple messages, such as “hi,” “let’s play,” or “leave me alone.” These devices are not appropriate for individuals who have more than a few things to say or who have the ability to generate complex thoughts and feelings.

There are a number of more sophisticated digital devices available as well. These include the DynavoxM<sup>3</sup>, Chatbox40 (Fig. 73-10), Springboard, and others. These devices have the capacity to encode several minutes of live voice and are often used by individuals who are not yet literate, have developmental disabilities, or simply wish to have a simpler device to use when going to the store or out to eat.

At the high end of AAC systems are the synthesized speech devices (Fig. 73-11). These voice output systems use built-in speech synthesis to speak messages that have been typed and previously stored into the device. They are capable of encoding several thousand words, phrases, and sentences. AAC devices such as these are frequently designed to provide an alternate access to the computer and control appliances

**FIGURE 73-10.** The Chatbox. (Courtesy of David Hershberger, Salttillo Corporation, Millersburg, Ohio.)

**FIGURE 73-11.** The Vantage Communication Device. (Courtesy of Barry Romich, Prentke Romich Company, Wooster, Ohio.)

such as TVs, door openers, and other electrical items found in many environments. Four popular text-to-speech devices are the ECO-14, LightWriter (Fig. 73-12), Tango, and the VMax. It is important to note that these AAC systems can cost thousands of dollars. But more importantly, they also form a critical link to the world for individuals with severe expressive communication impairments.

All of the AAC devices on the market can be activated through direct selection using either a finger or other pointing device, such as a head or mouth stick. A large number of the digital and text-to-speech devices can be activated using either direct selection or an alternate input mode. Alternate input includes all of the switches described above, as well as other additional infrared and wireless switches currently on the market. When an individual with a severe motor impairment and severe expressive communication impairment chooses to

**FIGURE 73-12.** Using the LightWriter. (Courtesy of Marlin Cohrs, Assistive Technology Partners, Department of Rehabilitation Medicine, University of Colorado Health Sciences Center.)

use a switch to access the AAC device, the device can be preset to scan.

The most commonly used switch access method is called row column scanning. In this method, the end user starts by activating a switch to begin the scan. When the correct row is highlighted, he/she hits the switch again to start the lights scanning across the row (hence column). When the correct button is highlighted, the user hits the switch again to activate the chosen button. As can be surmised, using a scanning system to activate an AAC device can be a slow and tedious process. For many individuals, however, this method provides the only available access to spoken and written communication, and for those select persons it is highly prized as a window to the world.

One of the more vigorous debates within the field of AAC centers around the encoding or mapping strategies used to represent language on a communication device. Currently available systems vary greatly in vocabulary storage and retrieval methods, but all systems are based on communication symbols, whether orthographic or pictographic. Symbols vary in their transparency (guessability) and translucency (learnability). In order to select a set of symbols for an individual's communication system, it is important to match these factors with the individual's cognitive and perceptual abilities.

Additionally, the world of technology moves at a very rapid pace. AAC devices currently on the market have been designed using today's technologies. As more and more innovations become available, such as cell phones, text messaging, and wireless global positioning systems (GPS), the capabilities and flexibility of these devices will change. As with all technologies, it is important that clinicians and practitioners remain current on these and future technology developments.

## AT FOR VISUAL IMPAIRMENTS, INCLUDING BLINDNESS

The term *visual impairment* technically encompasses all degrees of permanent vision loss, including total blindness, which affects a person's ability to perform the usual tasks of daily life. *Low vision* refers to a vision loss that is severe enough to impede performance of everyday tasks but still allows some useful visual discrimination. Low vision cannot be corrected to normal by regular eyeglasses or contact lenses.

For individuals with visual impairments, there are a variety of AT devices and strategies available to assist them to perform daily activities such as reading (Fig. 73-13), writing, daily care, mobility, and recreational activities. Among the low-tech solutions are simple handheld magnifiers, the use of large print, or mobility devices (e.g., long cane) for safe and efficient travel. High-contrast tape or markers can be used to indicate what an item is or where it is located within a physical plant.

Other low-tech devices include items such as wind chimes to facilitate direction finding, using easily legible type fonts such as Verdana (16 point or larger), and using vanilla- or beige-colored paper rather than white to improve visibility of

**FIGURE 73-13.** Low-tech magnification. (Courtesy of Marlin Cohrs, Assistive Technology Partners, Department of Rehabilitation Medicine, University of Colorado Health Sciences Center.)

text. For children and adults interested in recreational activities, solutions include beeper balls, three-dimensional puzzles, and “Braille Trails” specifically designed to improve access to wilderness and other outdoor activities (Fig. 73-14).

Many restaurants now provide large-print, Braille, and picture-based menus for customers with a variety of abilities. Books on tape are another readily available resource for

**FIGURE 73-14.** Low-tech recreation aids. (Courtesy of Marlin Cohrs, Assistive Technology Partners, Department of Rehabilitation Medicine, University of Colorado Health Sciences Center.)

**TABLE 73.1 Resources: American Federation for the Blind (AFB)**

individuals with severe visual impairments. Libraries that provide print materials in alternate formats for persons who have visual and learning impairments can arrange to have textbooks and other materials translated into various formats. For more information, contact the American Federation for the Blind (Table 73-1).

High-tech solutions for persons with visual impairments can include a computer outfitted with a speech synthesizer and software that allows text, software menus, and other writing on the computer screen to be heard aloud by the person unable to see well enough to read the computer screen (Jaws, Outspoken). Brailled text, although somewhat less popular than in the years past, as a result of technology advances, is still the first choice of many individuals to facilitate reading of print material.

For individuals with some degree of visual ability, screen magnification software is available for computers. Zoomtext and Zoomtext Xtra (Fig. 73-15) are two of the more popular versions of screen magnification programs. These software

enable the end user to choose the amount and type of magnification he or she prefers for optimal computer access.

A recent addition to the screen magnification software list is one called Bigshot. This software is less expensive (\$199) and provides fewer features. However, it appears to be a nice alternative for computer users who do not need access to the more sophisticated computer functions, and it is affordable for public facilities such as libraries that wish to provide reasonable accommodations for customers accessing information databases.

## AT FOR LEARNING AND COGNITION

Children and adults can present with a variety of learning and cognitive impairments resulting from either acquired or developmental disabilities. Not only can AT provide important accommodations for those with disabilities of all types, it can also become a critical tool to be used during recovery or acquisition of functional skill sets. For those with learning disabilities, there are a wide range of abilities that may benefit from an AT solution.

For example, many children with learning and cognitive impairments struggle with developing literacy skills. Fortunately, there are a number of both low- and high-technology solutions available to assist them. Many benefit from the use of specially designed software programs that *predict* the word or phrase they are trying to spell as they type the first letter(s) of a word (Co:Writer). Other software programs provide highlighted text and voice output so they are able to hear the words that they are generating (Write Outloud, Kurzweil 3000) on the computer. Individuals who are unable to read print materials often use some of the software solutions mentioned in the previous section, such as Jaws for voice output or books on tape.

Voice recognition has become a popular request both for persons with mobility impairments who are unable to type using their hands and for individuals whose learning disabilities are so significant they are unable to develop literacy skills. Voice recognition software enables an individual to speak into a microphone in order to input words, phrases, and sentences

**FIGURE 73-15.** Zoomtext Xtra. (Courtesy of Marlin Cohrs, Assistive Technology Partners, Department of Rehabilitation Medicine, University of Colorado Health Sciences Center.)

into standard computer word processing programs such as Microsoft Word. Although a bit trickier, voice recognition can be used for input and control functions for other software, such as database programs and Windows.

Although voice recognition software is a rapidly developing technology, it is important to remember that it takes a fifth- to sixth-grade reading ability to train the standard software, simply because the individual's voice file cannot be developed unless he or she uses the standard training package that comes with the software. Dragon Systems has developed a version for children, but its success rate for children with learning and other cognitive disabilities has not yet been published. In addition, ambient noise, such as in a typical classroom, as well as fluctuating vocal abilities (e.g., fatigue) found in many individuals with disabilities will have an impact on the accuracy of the voice recognition. In general, it takes more than 20 hours to train the software to an acceptable level of accuracy (>90%). Although caution is in order when prescribing this type of software, the rapid pace of development bodes well for future use of this solution for persons with disabilities.

Low-tech adaptations for persons with learning and/or cognitive impairments can include colored highlighter tape, pencil grips, enlarged text, and other easy modifications, such as using a copy holder to hold print materials for easy viewing. Reminder lists with important times, places, and activities highlighted with a marker are often useful for individuals who need subtle memory prompt to be in the right place at the right time.

Recent technology developments include the handheld personal digital assistants or PDAs. AT software developers (AbleLink Technologies, Inc.) have taken this technology a step further by developing a software application named PocketCoach (Fig. 73-16) that provides auditory prompts for individuals with cognitive disabilities. This software can be set up to remind someone what step they need to take next. It can be used for something as simple as a vocational task, such as mopping a floor, all the way to the complexity of prompting someone through the steps of a math problem. The latest edition of this software combines voice prompts with visual prompts (Visual Assistant). The individual setting up the system can simply take a picture with the accompanying digital camera and combine the pictures with digitally recorded voice prompts to further facilitate memory and cognition.

A number of software packages are available for these populations that focus on a range of topics, including academics, money management, personal skills development, behavior training, development of cognitive skills, memory improvement, problem solving, time concepts, safety awareness, speech and language therapy, telephone usage, recreation, and games. For individuals with cognitive and learning impairments, a number of simple techniques can be kept in mind when evaluating or designing activities and materials for use by persons with cognitive and learning impairments. Table 73-2 includes some components of accessible interfaces to keep in mind.

**FIGURE 73-16.** The PocketCoach. (Courtesy of Dan Davies, AbleLink Technologies, Inc. Colorado Springs, Colorado.)

## AT FOR HEARING

For an individual who is deaf or hard of hearing, there are two major effects of hearing loss: lack of auditory input and compromised ability to monitor speech output. AT devices, such as hearing aids and FM systems can often be used to facilitate both auditory input and speech output. Other types of AT devices provide a visual representation of the auditory signal. These include flashing lights to indicate an emergency alarm (fire, tornado), the phone ringing, or someone at the door.

Low-technology solutions or technology-free solutions might include use of sign language or other visual representation of the spoken word or providing information in a print format. Another recent adaptation is computer-assisted translation. Referred to by the acronym CART (Computer-Assisted Real-time Translation or Communication Access Real-time Technology), this solution involves a specially trained typist who captures or types the discourse of the speaker(s) on a computer that is then projected onto a monitor or other display. A variation of CART is computer-assisted note taking, when the primary purpose is to provide a written record for a student or employee.

Environmental adaptations can frequently support individuals who are deaf or hard of hearing. For example, when speaking to someone who has difficulty hearing, do not stand

**TABLE 73.2** Components of Accessible Interfaces*Simplicity* of layout, operation, and appearance

- Is the interface crowded, complex, or otherwise overwhelming?
- Does the interface require complex mouse actions or keystroke combinations?
- Is the language level of the interface too complex for the user?

*Consistency* of critical elements in the interface

- Are interface elements and controls located consistently throughout the application?
- Are interface elements and controls activated in the same manner throughout the application?

*Saliency* of active elements

- Is the user directed visually or otherwise toward the central content of the interface?
- Is key information highlighted?
- Is there a minimum of competing information?
- Is it clear to the user when actions or changes occur in the interface?

*Intuitive* operation

- Is the operation of the software obvious to the user?
- Is the selection of user interface components simple and direct?
- Is it clear to the user that the interface is responding to his or her input?
- Is there clear feedback when the application is busy completing a task?

*Organization*

- Are similar functions grouped logically together?
- Does the organization of the interface make sense visually?

*Adaptability*

- Does the interface offer a choice of modalities for the user (e.g., can on-screen text be read aloud)?
- Can interface elements be added or removed easily to adjust to a user's abilities?
- Does the interface offer context-sensitive help, such as tool tips?
- Are on-screen instructions provided?
- Are cues provided automatically to the user if he or she waits for assistance?
- Is there a timed response?

*Recoverability*

- Can the user easily recover from an error?
- Is clear warning provided if an action cannot be undone?
- Can the user explore the interface safely without causing instability?

in front of a light source (windows, lamps, etc.), and do not overexaggerate lip movements, but do include gestures, which can be helpful. For individuals who wear hearing aids, there are a number of additional technologies that can facilitate hearing in large rooms or in crowded environments, such as a restaurant. The Conference Mate and Whisper Voice are two products especially designed for this issue. The person with the hearing loss wears a neck loop (it looks much like a bolo tie). In the case of the Conference Mate, a small octagonal device is placed on a convenient table. This device picks up voices within the room that are transmitted to the neck loop and then to the hearing aid for better reception. Although it may sound cumbersome, it can be an excellent solution for office- and school-based environments. The Whisper Voice works much the same way, except the device contains a small microphone and is portable. It can be passed from one speaker to another, with sound transmitted to the neck loop and then to the hearing aid for amplification. Chapter 15, Speech, Languages, Swallowing and Auditory Rehabilitation contain additional information on hearing loss and auditory rehabilitation.

## AT FOR ERGONOMICS AND PREVENTION OF SECONDARY INJURIES

A rapidly growing area of concern for AT practitioners is the development of repetitive motion disorders. For many persons with disabilities, the use of computer keyboards and other technology presents an opportunity for secondary injuries to occur. Computer desks, tables, and chairs used in computer labs, classrooms, and at the office do not always match the physical needs of the end user. When those with disabilities (and those without) are not positioned properly and then spend hours repetitively performing the same motor movement, they can and do develop (incur) injuries.

An entire industry of AT has developed over the past few years dealing with repetitive motion disorders. Potential solutions for someone demonstrating this type of impairment include raising or lowering a chair or desk for the appropriate fit, implementing routine breaks within activities for the individual to move about or do something different, lumbar and other supports, specially designed ergonomic keyboards, and other ATs.

**TABLE 73.3 Internet-Based Resources**

UCLA Ergonomics	Guide to the field of ergonomics, including discussions, resources, links, and definitions	<a href="http://ergonomics.ucla.edu/">http://ergonomics.ucla.edu/</a>

Many of the ATs described in earlier sections, such as voice recognition software, alternate and specially designed ergonomic keyboards, and strategies designed to minimize keystrokes and other repetitive movements can also provide useful solutions for individuals with repetitive stress injuries. There are a number of Internet-based resources available that target ergonomic issues, such as those found in Table 73-3.

## ELECTRONIC AIDS TO DAILY LIVING

Electronic Aids to Daily Living (EADLs), also described as environmental control units, provide alternative control of electrical and battery operated devices within the environment. These devices may include the TV, VCR, stereo, lights, appliances, telephone, door, electric bed, and more. EADLs are designed to improve independence of ADLs. EADLs are primarily used in the home, but can also be used at work and school.

EADLs provide alternative control and are designed for persons who are unable to use standard controls such as light switches or other electronic or battery-operated appliances and fixtures. EADLs can be helpful for persons with physical and cognitive disabilities. For example, a person who has aphasia and motor impairments that are due to stroke may not be able to easily select a new TV channel. This person may benefit from a solution as simple as a standard TV remote control.

A person with cerebral palsy may have difficulty with small buttons on a remote control. This person may benefit from an EADL that is accessed by a switch to scan choices. Persons of all ages can benefit from this technology as well. For example, entry level EADLs provide alternative control of toys for very young children.

EADLs are controlled by three different access methods: direct, switch, and voice. Direct access is generally finger-to-button, as on a standard remote control. Some EADLs have enlarged buttons or keyguards to assist direct access. Enlarged

buttons can also make the buttons easier to see. Typically, individuals who use direct EADLs have fair to good fine motor control and vision.

In switch access, any type of switch can be placed at the best location for activation by the person. The first switch activation begins a scan of choices, usually of general categories (i.e., TV, lights, phone). The second switch activation chooses one of these categories. Choices within that category are now scanned (i.e., channel up, channel down, mute). A third switch activation selects the desired function, and the signal is sent to the TV. Most of these systems have visual displays with small text in English (although some EADLs are available in other languages) and no speech feedback. The person generally must have good sequencing skills and vision and be able to read.

Voice-operated EADLs respond to verbal commands. For example, if the user says "TV on," a signal is immediately sent to the TV to turn it on. The individual using the device needs to have a consistent, understandable voice to operate these EADLs. They must also remember the available commands or be able to read a list to remind themselves. A person with a high-level spinal cord injury is a typical patient who could benefit from this type of device.

Many augmentative communication devices are capable of sending signals to control devices within the home environment. This can be advantageous for several reasons. First, because the EADL capability is built in, no additional funding is needed. Second, these AAC devices allow the use of larger text, graphics, and auditory scanning. Auditory scanning verbally announces each choice as it is scanned. Depending on the AAC device, these auditory prompts can even be recorded in another language. This can be very helpful for individuals with low or no vision, who need prompts to assist with memory or sequencing challenges, or who do not read (or do not read English). If they are already using a communication device, these features can be easily programmed to increase independence in the home. Some individuals who do not require an AAC device still use one solely for the EADL features because

of the visual and cognitive advantages. AAC devices can be accessed directly by switch scanning, mouse control, or joystick.

Finally, software and hardware are available for computers to provide control of devices within the environment. Typically, this technology is designed for computer users who are interested in automating their home. These EADLs are not designed for persons with disabilities and can be challenging to use both cognitively and via motor control. Whatever method a person is using to access his or her computer (i.e., keyboard) is what is used to access the EADL features.

People must both feel and be safe in their home, especially if they are left alone for any period of time. Primary safety concerns are control of the telephone and door opener. The person with a disability must have independent access to both, if at all possible. The telephone is crucial for calling emergency personnel (i.e., medical emergency, possible burglary), calling when an attendant does not show up, and calling when a caregiver becomes incapacitated. Of course, phone access is also dependent on his or her ability to judge an emergency appropriately and call emergency services when warranted. The phone must have battery backup, as some emergencies are linked to power outages.

If the person is mobile and the home entrance is accessible, a power door opener may be necessary. However, if the individual has cognitive limitations affecting judgment and should not leave the home without supervision, independent control of the door may not be appropriate. Independent control of a door opener is crucial for leaving the home in an emergency such as a fire and letting in caregivers and visitors so safety and security are not compromised.

### Considerations in EADL Selection

Features that are essential to consider in EADL selection are (a) portability, (b) whether the client needs to use the EADL from their bed, and (c) safety. A portable device is very important for an individual who is mobile within the home (i.e., driving a power wheelchair) and for people who need to use the EADL from more than one position, such as from a wheelchair and also from bed. A portable EADL can be moved from one location to another.

Accessing the EADL from bed is very important for many persons with disabilities. Alerting a caregiver of a need in the night, controlling an electric bed, turning on a light, and turning on some quiet music to help someone go to sleep are just a few examples. Motor control can change dramatically from sitting to lying down, which may require a different access method in general or two different access methods (i.e., hand switch in the wheelchair and head switch in bed).

There are a number of important questions to be discussed during the EADL selection process. These include

1. What environments will the person be in, and how much time is spent in each setting?
2. What appliances or devices need to be accessed?

3. Will needs and abilities change throughout the day or in different environments?
4. What are the individual's cognitive and sensory abilities? (17)

AT specialists should assess for the most appropriate EADL based on what devices the person would like to control, as well as motor, cognitive, and sensory skills. The AT specialist or the AT supplier or vendor can also assist with procuring funding, installing equipment in the home, and training the end user and caregivers in its use.

Appropriately prescribed EADLs result in a more productive and satisfying lifestyle. In the hospital setting, EADLs allow patients to experience greater independence and can decrease the level of required nursing supervision and support. In the home, an EADL allows an individual more independence and flexibility while demonstrating the cost benefit of decreased home health care and assistance.

### TEAMING AND AT

“Teaming means you work together, no matter what. You do it because you’ll come up with better ideas. And, if (or when) you disagree, you just figure it out—without fighting” (18). Equal participation in the collaborative teamwork process by the person with a disability, family members, and service providers is critical for individuals to achieve their goals. As it is in so many areas of physical medicine and rehabilitation, AT services are delivered in a wide variety of settings, including comprehensive medical rehabilitation centers, university-affiliated clinics, state agency-based AT programs, private rehabilitation engineering and technology firms, and nonprofit disability organizations (19). Because AT is a relatively new field and preservice and in-service preparation is just beginning to register an impact, persons with disabilities may encounter difficulty locating experienced and credentialed professionals to deliver AT services.

A transdisciplinary model of service delivery is preferred as it provides a larger pool of resources and expertise. The team may include occupational and physical therapists, rehabilitation engineers, speech language pathologists, physiatrists, case managers, and other professionals identified as important to meeting the individualized goals of the person with a disability. It is critical that the team includes as *recognized members* the person with the disability(s), and his or her family and significant others when appropriate. It is also critical that at least one member of the team has some background knowledge and training in the field of AT. There are a number of university and online courses available for professionals to build expertise as well as resources in the field of AT.

The field of AT, like many other growing professions, is working to develop standards of practice and credentialing opportunities. The Rehabilitation Engineering and Assistive Technology Society of North America (RESNA), an interdisciplinary association for the advancement of rehabilitation and

**TABLE 73.4** Credentialing Specialties in AT

Specialty	Definition
Rehabilitation engineering technologist	Person who applies engineering principles to the design, modification, customization, and/or fabrication of assistive technologies for persons with disabilities
AT practitioner (ATP)	Service provider primarily involved in analysis of a consumer's needs and training in use of a particular device
AT supplier (ATS)	Service provider involved in the sales and service of commercially available devices

AT, has developed guidelines and credentialing examinations for three categories of specialists in AT (Table 73-4).

For more information about the credentialing process and criteria for credentialing, contact RESNA at <http://www.resna.org>. A number of universities throughout the United States and Canada offer training in AT for a wide range of audiences. Table 73-5 lists only a few of the available options. For more information, visit the Web and type *assistive technology training* into the search engine.

## ASSESSMENT USING A TEAM APPROACH

The goal of any AT evaluation is to determine whether the individual receiving this service has the potential, and the desire, to benefit from AT devices and services at home, school, work, or play. Other outcomes of an AT evaluation include providing a safe and supportive environment for the person with a disability and his or her family to learn about and review available assistive devices; identifying necessary AT services such as training, modification, etc., that may be necessary for the equipment to be effective; and developing a potential list of recommended devices for trial usage before a final determination is made. Also, the individual and family, as well as the involved professionals, should specify exactly what they hope

to achieve as a result of the evaluation (i.e., equipment ideas, potential success with vocational or educational objectives).

When selecting team members to conduct an AT evaluation, appropriate disciplines should be chosen based on the identified needs of the person with the disability. For example, if the individual presents with both severe motor and communication impairments, then an occupational or physical therapist with expertise in AT, as well as a speech-language pathologist with a background in working with persons with severe communication impairments and alternative forms of communication, should be included as members of the team. If a cognitive impairment has been identified during the intake process, someone versed in learning processes such as a psychologist, neurolinguist, teacher, or special educator might be appropriate members of the team. If there is an ergonomic issue (i.e., carpal tunnel syndrome), an evaluator with training in ergonomic assessment or a background in physical or occupational therapy is a necessary component for a successful experience.

It is *not* appropriate for an AT vendor to be called in to perform the AT evaluation. Although vendors can and should be considered as identified members of the team, it must be recognized that they have an inherent conflict of interest. They are there to sell products. When requested by the team, vendors *should* demonstrate their products, discuss pertinent features, and assist in setting up the equipment for evaluation and trial usage. However, other team members, including the end user and their family, should carry out the actual evaluation and make the final recommendation(s).

## Phase I of the Assessment Process

Knowledge within the field of AT continues to grow and change, sometimes on a daily basis. As this evolution continues, a number of important variables are being identified that directly impact whether the AT recommended by the assessment team will be used or abandoned by the consumer (9,20). As a result of this information, the evaluation process continues to be refined. Many researchers are working to develop standardized AT measurement tools (9,21,22), but the fact remains there are few available resources to guide practitioners who have not received formalized training in AT.

**TABLE 73.5** Sample of Available University-Based Training Programs in AT

George Mason University	<a href="http://chd.gse.gmu.edu/chdinfo/training.htm">http://chd.gse.gmu.edu/chdinfo/training.htm</a>
University of Colorado Health Sciences Center	<a href="http://www.uchsc.edu/atp">http://www.uchsc.edu/atp</a>
University of Kentucky	<a href="http://www.ukv.edu/">http://www.ukv.edu/</a>

As mentioned earlier in this chapter, the number one reason AT is abandoned is because the needs and preferences of the consumer were not taken into account during the evaluation process. Other reasons cited for abandonment of devices include

- Changes in consumer functional abilities or activities
- Lack of consumer motivation to use the device or do the task
- Lack of meaningful training on how to use the device
- Ineffective device performance or frequent breakdown
- Environmental obstacles to use, such as narrow doorways
- Lack of access to and information about repair and maintenance
- Lack of sufficient need for the device functions
- Device aesthetics, devices, weight, size, and appearance (8)

Careful review of these factors suggests that many of these issues can be considered during the evaluation process. At the University of Colorado Denver, School of Medicine, the assessment protocol has evolved from a group of practitioners trying any number of devices with the individual to a team process that starts by leaving the technology out of sight. The process about to be described may sound laborious and cumbersome. With practice, we have reduced the time necessary for the evaluation process and have increased the likelihood that the individual who will be using it selects the appropriate technology. In addition, this process has decreased both installation and follow-up training time and has resulted in improved outcomes for end users.

Phase I of the assessment process is initiated once a referral is received. Standard intake information is collected, usually over the phone that provides the name, primary diagnosis, age, reason for referral, etc. In the majority of cases, cognitive, motor, vision, and other standard clinical assessments have already been performed, and a release of information is requested from the individual or his or her caregivers for this information to be forwarded to the team. If it has not previously occurred, these evaluations are scheduled as a component of Phase II of the assessment process.

Based on the preliminary information, an appropriate team of professionals is assembled and a date chosen for the evaluation. The team leader takes responsibility for ensuring that the individual with the disability, his or her family, and any other significant individuals are invited to the evaluation. It is not unusual to vary the schedule to meet the needs of the family rather than the professionals.

When the time arrives for the evaluation, the team members are invited to gather and spend some time getting to know the individual. Using methods described by Cook and Hussey (22) and Galvin and Scherer (8), the team first identifies the life roles of the consumer (e.g., student, brother, musician, etc.). Then the specific activities engaged in by the individual to fulfill that life role are identified. For example, if he is a brother, then that means he may play hide and seek with a sibling, squabble over toys, or otherwise engage in brotherly activities. If he is a musician, then he may want or need to

have access to musical instruments, sheet music, or simply a radio.

Next, the team identifies any problems that may occur during these activities. For example, the musician may not have enough hand control to play the piano or may experience visual or cognitive difficulties with sheet music. Specific questions are asked regarding where and when these difficulties occur (activity limitations). Perhaps problems occur when the individual is tired, or not properly positioned, or when he or she tries to communicate with others. The individual is also asked to describe instances of success with these activities and to discuss what made them successful (prior history with and without technology). Interestingly enough, the team by now is usually able to recognize patterns of success and failure from the individual's perspective, as common themes across environments emerge.

Finally, we ask the team to prioritize the order in which we can address identified barriers to participation, and a *specific* plan of action is developed. Within the specific plan of action, "must statements" are also developed. For example, the device *must* have a visible display in sunlight, or the technology chosen *must* weigh less than 2 lb. In one instance, the must statement read, "It *must* be purple."

It is at this point that the team may be reconfigured. For example, if the individual is not properly seated and positioned, they are referred first to the occupational or physical therapist for a seating and positioning evaluation before any other technology issues being addressed. At all times, the configuration of the team includes the individual being assessed and the caregivers as the primary members to be consulted.

In many instances, various members of the team in collaboration with others determine that further assessment from their perspective is not warranted for the technology component to proceed. In other situations, it is determined that additional team members who were not previously considered should be invited to participate (e.g., vision specialist).

## Phase II of the AT Assessment

Once the team has agreed on the specific plan of action and those things that must occur, phase II of the assessment process begins. The person with a disability and his/her caregivers are asked to preview any number of assistive devices that may serve to reduce activity limitations and increase participation in their chosen environments. These ATs are tried with the individual, and various adaptations, modifications, and setups are explored to ensure an appropriate match of the technology to the individual is made.

It is at this point that the AT skill sets of the clinician become critical. If trial devices are not properly configured or if the wrong information is given to the consumer, then they will be unable to make an appropriate selection. Because so many devices require extensive training and follow-up, it is also critical that realistic information regarding training issues (including learning time) is provided and appropriate resources within the local community be identified.

In a number of instances, the technology that appears to be optimal for an individual does not carry with it the appropriate community supports. In those cases, it is often advantageous to work first to identify local resources or local AT professionals willing to receive additional training before sending the device home with the end user. At all times, the end user and his or her families should be informed and updated so that they can make the final decision regarding when and where they wish the equipment to be delivered.

With very few exceptions, the wise course of action involves borrowing or renting the equipment before a final purchase decision. For many individuals with disabilities, the actual use of various technologies on a day-to-day basis elicits new problems that must be resolved. Unexpected benefits, including changes in role and status, also occur as a result of improved functioning. In some cases, these *unexpected benefits* create an entirely new set of problems that must be addressed. For most, these disruptions can be resolved with time and energy. Others decide that they either prefer the old way of doing things, or they are interested in adding or changing the technology once they have had a chance to experiment with it in different settings.

### Writing the Evaluation Report

When writing the evaluation report for an AT assessment, it is important to ensure that a number of items are included. First and foremost, case managers, educators, and others unfamiliar with assistive technologies appreciate layman's terms when discussing the need for AT and what it will accomplish.

In cases in which medical insurance is being used to purchase the technology, it is critical to document the actual medical necessity for the device(s). For example, "Mrs. Smith will use this device to communicate her health care needs and

to meet the functional goals outlined in the attached report." In instances when the evaluation was requested to determine educational or vocational benefit with assistive devices, it is important to document how these specific needs will be met with the prescribed equipment.

It is extremely important that all components of the assistive devices be included (e.g., cables, ancillary peripherals, or consumable supplies) in the list of recommended equipment. In many instances, devices are recommended for purchase as a "system." When this occurs, acquisition and implementation can be delayed for months because an item was not included in the initial list. It is also important to include contact information for the various vendors who sell the equipment. Many purchasers are unfamiliar with these companies, and acquisition can be delayed for months if this information is not included in the report.

### FUNDING AT

The funding sources for AT fall into several basic categories (Table 73-6). One source to be investigated is private or government medical insurance. Medical insurance defines AT as medical equipment necessary for treatment of a specific illness or injury. A physician's prescription is usually required. When writing a prescription for an AT device, it is important that the physician is aware of the costs and benefits of the devices he or she is prescribing and is prepared to justify his or her prescriptions to third-party payers. Funding includes not only the initial cost of the device, but the expense involved in equipment maintenance and patient education, as well as the potential economic benefits it provides to the patient (e.g., return to work).

According to a publication sponsored by the American Medical Association (23), the following items (reprinted with

**TABLE 73.6 Potential Funding Sources for AT**

Public Programs	Alternative Financing	U.S. Tax Code
Medicare	Private insurance	Medical care expense deduction
Medicaid—Early and Periodic Screening, Diagnosis, and Treatment (EPSDT)	Private foundations	Business deductions
State grants	State loan programs	Americans with Disabilities Act credit for business
Individuals with Disabilities Education Act (Parts B and C)	Employee accommodation programs	Charitable contributions deduction
Vocational rehabilitation state grants, including Title VH, Chapter 2	Corporate-sponsored loans	Targeted jobs tax credit
The Developmental Disabilities state grants	Community reinvestment programs	
Workers Compensation Programs	Family and friends	
Social Security Supplemental Security Income PASS Program	Religious organizations	
CHAMPUS/TRI-CARE	Community groups	
Department of Veterans Affairs	Service clubs and advocacy organizations	

permission) should be taken into account when prescribing AT and certifying medical necessity:

1. The physician must provide evidence of individual medical necessity.
2. An “appropriate” prescription is one that takes into consideration the comprehensive assessment process, including motivation and availability of training, the potential patient functional outcome, and the cost/benefit of available products.
3. Physicians should be prepared to provide sufficient information to insurance companies to ensure approval. Dialogue is often necessary to show medical necessity of complex assistive technologies (power wheelchairs, computer-based environmental control systems).
4. Basic knowledge of AT reimbursement for patient and physician includes familiarity with established medical necessity forms and prior authorization procedures.
5. Avoid making static decisions on a dynamic problem; anticipate future need.
6. Base decision on both expected performance and durability of the device.

### Documentation in the Medical Record

In addition to prescribing and certifying medical necessity on various forms, physicians must be sure to maintain complete patient records that include the following information:

- Patient diagnosis or diagnoses
- Duration of the patient’s condition
- Expected clinical course
- Prognosis
- Nature and extent of functional limitations
- Therapeutic interventions and results
- Past experience with related items
- Consultations and reports from other physicians, interdisciplinary team, home health agencies, etc.
- Complete listing of all assistive devices the patient is using, including copies of prescriptions and certification forms or letters
- Tracking system for device performance, including follow-up assessment schedules and lists of professional and vendor names to contact if problems occur

### Letters of Medical Necessity

These letters should include the following areas:

1. Diagnoses ICD-10-CM codes
2. Functional limitation(s) (a partial list of disabilities as examples follows):
  - Balance disorder
  - Developmental delay
  - Hypotonia
  - Joint deformity or instability
  - Hemiparesis
  - Side affected or bilateral
  - Diaparesis
  - Paraparesis

3. “Because of the patient’s functional limitation, he/she is unable to...”
  - a. Perform
    - i. ADLs
    - ii. Instrumental ADLs
    - iii. ADLs and functional mobility
    - iv. Functional mobility
    - v. Work activities
  - b. Communicate
    - i. Verbally
    - ii. In writing
    - iii. Independently over the phone
4. Use of equipment “The use of the equipment will/allow the patient to...”
  - Function independently
  - Function independently with the device/equipment
  - Perform independent wheelchair mobility in the home
  - Perform independent wheelchair mobility in the home and community
  - Return home
  - Be required as a lifetime medical need (if shorter duration, explain need)
  - Improve the patient’s functional ability
5. Description of equipment (a partial list as examples follows):
  - a. Wheelchair
  - b. Wheelchair frame
    - i. Electric
    - ii. Manual
    - iii. Manual backup
    - iv. One-arm drive
    - v. Lightweight
    - vi. Nonstandard
    - vii. Reclining
    - viii. Miscellaneous
  - c. Other
    - i. Bathing aids
    - ii. Toileting aids
    - iii. High-technology vision enhancers
    - iv. Other hearing assistive devices
    - v. Hospital bed
    - vi. Stander
6. Rationale (a partial list as examples follows):
  - Safety or safe positioning for an activity
  - Cost-effectiveness in prevention of secondary complications (e.g., pressure sores)
  - Mobility restrictions preventing independent activity
  - Access to areas in home, such as bathroom and kitchen
  - Access to workplace, school
  - Duration of expected use
  - Past experience, interventions, and results (failure of less expensive solutions)
  - Duration of expected use
  - Goals and benefits to patient

AT is usually covered under policy provisions for durable medical equipment, orthotics and prosthetics, or daily living

and mobility aids. With private insurance, AT providers request funding under the specific provisions of the individual policy, appealing any denials (an inevitable) and offering medical justification for coverage. With government insurance policies, such as Medicaid and Medicare, coverage is based on existing law and regulations. In 2002, regulations were promulgated by Medicare to include coverage of AAC devices (24).

Information on covered services and how to request funding is available from the Medicaid programs in individual states and from the regional offices for Medicare. AT professionals and other health care providers should continually advocate for adequate coverage of AT in all health care plans.

Funding of AT is also available from other federal and state government entities, such as the Veterans Administration, State Vocational Rehabilitation, Rehabilitation Services Administration, State Independent Living Rehabilitation Centers, and State Education Services. Local school districts may fund education-related AT for children. Each agency or program sets criteria for the funding of AT based on the mission of the agency and the purpose of the technology. For example, vocational rehabilitation agencies generally pay for devices to facilitate gainful employment, and education program funding is directed toward enhancing the client's performance in school.

Private funding is often available through subsidized loan programs, churches, charitable organizations, and disability-related nonprofit groups. The AT provider must keep abreast of the requirements of various funding sources in order to direct the client to appropriate organizations. Often a combination of funding from several sources is needed to reduce personal out-of-pocket costs. Because funding for replacement of AT devices is also difficult to obtain, careful selection of the initial device is required. Providers can also assist clients by considering funding when making equipment recommendations by including both low- and high-cost alternatives with their relative advantages. Funding is generally available for AT, but persistence and advocacy by the AT provider are required for success (25,26).

## MEASURING OUTCOMES IN AT

The study of the impact of AT devices for individuals with disabilities poses a challenge in outcomes research. The field itself is a multidisciplinary area of study encompassing medicine, rehabilitation, psychology, education, engineering, and biotechnology specialties, and involves physical, cognitive, psychosocial, sensory, and physiological effects. Consequently, there is a lack of consistency in what has been studied, how the outcomes have been measured, and where the results have been recorded. In the field of AT, there is also a paucity of outcomes measurement research in general (27).

More than 10 years ago, Frank DeRuyter of the Rancho Los Amigos Medical Center in Downey, California, stated that "evaluating AT services to demonstrate quality or to measure outcomes is the ethical obligation of the entire AT community"

(28, p. 3). He went on to remind us that the systematic application of outcomes management research within AT has been fragmented and limited at best, and suggested it is incumbent upon all stakeholders in the AT community to evaluate the value and outcomes in all aspects of services delivery. In 1996, RESNA dedicated an entire issue to AT outcomes. In his editorial, Larry Trachtman again reminded AT professionals to develop a methodology for measuring and reporting outcomes. He argued that no accepted way exists to collect data in order to verify trends or to support or refute practices. As a field, there is little or no agreement on the measures, data collections points, or even the desired outcomes (27, pp. 67–68).

Persons with functional limitations and the AT devices provided by professionals do not operate in a vacuum. They exist on a broad continuum and are impacted by such things as environmental and psychosocial issues, family finances, cultural differences, and other contextual factors. Services are often fragmented, with many consumers receiving interventions from any number of teams and facilities. It is not unusual to hear families talk about their school team, hospital team, and any number of private therapists as independent service providers who do not interact. Rarely are discussions held regarding appropriateness of devices across environments, cost-effectiveness, or prevention of secondary conditions. General agreement within the field suggests that outcome measurement is a critical, unmet need. But a conceptual framework for developing measurement tools and measurement research has remained elusive (28–32). Studies of the treatment efficacy of AT devices and services have typically been relegated to single case study reports and occasional multiple case reports showing changes from baseline (33,34).

AT traditionally includes the prescription and implementation of devices for sensory augmentation (speech, hearing, vision, etc.), but in recent years, the concept of AT has been broadened to encompass any technology that can improve a person's function (35). This is an important distinction, because it places nonoperative rehabilitation interventions, such as orthotics, prosthetics, electrical stimulation, and functional neuromuscular stimulation, in the realm of AT.

The application of technology to improve human function has long been the goal of the AT professional. In many cases, clinicians working in AT have been the most successful at crossing traditional clinical boundaries to reach out to their health care partners who may be less familiar with AT, producing collaborations that are both innovative and productive. The AT specialist has the hands-on clinical experience to see what works and understands those factors leading to technology abandonment. Typical clinical practice, however, does not lend itself to the development of experimental methodologies to objectively evaluate patient performance with AT devices and services. Moreover, most AT clinicians do not have the resources to actively participate in a sustained program of research, nor are these behaviors emphasized as a component of clinical intervention in most training programs.

Despite this limitation, AT professionals and the AT service delivery model have been effective in getting technology into

the hands of the people who need it, creating a foundation for rehabilitation intervention service delivery in general. Because the AT specialist functions across disciplines, he or she is often the first to notice the impact of other treatment modalities. For example, it is typical for a child with an acquired disability to enter rehabilitation services with a variety of needs and assignments to various disciplines for treatment. It is often the AT specialist who notices incompatibilities between systems, such as a seating system with a lap tray that interferes with a child in the development of an alternate access method to a computer used to complete educational tasks.

In recent years, the National Institute on Disability and Rehabilitation Research and the National Institutes of Health's National Center for Medical Rehabilitation Research have begun to fund various research activities devoted to developing standardized outcomes measurement systems in order to determine the efficacy of various AT devices and services. The plan for these activities calls for the dissemination of information to individuals with disabilities, their families, caregivers, funding sources, and manufacturers. The field of AT is one of growth and excitement. Results from studies such as these are a welcome and necessary component for the continued development of this discipline.

## THE FUTURE OF ASSISTIVE TECHNOLOGIES

The future of assistive technologies and universal design is exciting to contemplate. Intensive research and development activities are focusing on human-robot interaction (HRI), GPS, and a wide range of other context aware sensor technologies. Advances in the commercial manufacturing industry is leading the way by designing cheaper, less intrusive support systems for persons without disabilities.

Researchers and engineers focused on these technologies are quickly taking advantage of new discoveries as well as adding to the body of knowledge and the array of products available for persons with disabilities. HRI is often frequent and intense in manufacturing and service environment(s). Utilizing a soft computing toolbox approach, especially with fuzzy set-based learning techniques, can be effectively adopted for modeling human behavior patterns as well as for processing human biosignals including facial expressions, hand/body gestures, Electromyogram (EMG), and so forth (36).

With over 600,000 people each year surviving a stroke, it has become the leading cause of serious long-term disability in the United States. Studies have proven through repetitive task training, neural circuits can be remapped, thus increasing the mobility of the patient. This fuels the emerging field of rehabilitation robotics. As technology advances, new therapy robots are developing that are increasingly compliant and captivating to use. One example is the robotic gait trainer (RGT) developed in the human machine integration laboratory at Arizona State University. The RGT is a tripod mechanism, where the patient's leg is the fixed link, controlled on a Matlab and Simulink platform. This device facilitates retraining of

gait and movement patterns impeded as a result of stroke or injury (37).

Context aware sensors and GPS systems are emerging technologies that can be useful in identifying where someone is; the status of his or her environment (temperature, location); and, changes in positioning, weight, etc. Utilization of these technologies can alert caregivers when a patient with dementia is attempting to open a door, taking a medication, lost, or otherwise impaired within their current environment. These same technologies are also proving to be an effective tool for persons with intellectual/developmental disabilities, MS, and other debilitating injuries or illnesses.

The field of AT is one of rapid change and growth. New technologies, new research possibilities, and a growing universal acceptance of AT devices and services support the recognition that persons with disabilities are persons with *abilities* who have much to contribute.

## ACKNOWLEDGMENTS

Funding for this chapter is due in large part to NIDRR grant no. H224A940014-01: Colorado Assistive Technology Project, State Grants for Technology Related Assistance.

Special thanks are also due to staff of Assistive Technology Partners, Department of Physical Medicine and Rehabilitation, University of Colorado Health Sciences Center, including Maureen Melonis, Jim Sandstrum, Pat McAleese, Marlin Cohrs, Julia Beems, Diane Brians, and Brian Simms. The authors also wish to thank Dr. Thomas W. King, Department of Communication Disorders, University of Wisconsin-Eau Claire; Department of Geriatric Health, American Medical Association; Michelle Lange for her work on the EADL section; and the previous AT chapter authors.

# Upper and Lower Extremity Prosthetics

Major limb amputation impacts multiple aspects of an individual's life: body image, self-care activities, mobility, psychosocial health, vocational, and avocational opportunities. Successful rehabilitation allows the individual with an amputation to return to their highest level of activity and function. Tempering expectations with reality, balancing the use of prosthetic technology with the individual's perceived needs, physical and cognitive capabilities, social support network, and financial resources are essential features of rehabilitative care.

Advances in the care and prosthetic restoration of the individual with an amputation have always come from multiple arenas: new surgical techniques, improvements in preoperative and postoperative management, advances in prosthetic technology, and better understanding of the psychosocial implications of limb loss. In the past decade, the greatest advances have taken place in the areas of prosthetic technologies, fabrication of prosthetic sockets, and improved components that more effectively replace the lost function of the extremity. Teams of health care providers in regional centers, who treat a large number of individuals with an amputation, are able to provide optimal prosthetic rehabilitation because of their combined experience (1). While such integrated teams are ideal, a less formal coordination of efforts between surgeons, physiatrists, prosthetists, and therapists in the community can provide effective care to most individuals with an amputation who lack access to specialized centers.

In this chapter, the causes of amputation, basic surgical issues, and the overall approach to the medical and physiatriac care of the individual with an amputation are reviewed. A discussion on the prosthetic management of amputation at different levels in both the lower and upper limbs follows to aid the practitioner in organizing the myriad options available for restoring the function of the lost limb. Finally, common problems, medical complications, and special issues in pediatric amputation are discussed.

## INCIDENCE AND ETIOLOGY

### Acquired Amputation

The etiology of limb loss influences the clinical treatment, management, and functional expectations of the individual with an amputation. Data from the Agency for Healthcare Research and Quality (AHRQ) and the Veterans Health Administration (VHA) from the late 1980s to the late 1990s estimates that

a total of 140,000 amputations are performed yearly in the United States (2,3). Acquired amputation accounts for 96% to 99% of all limb losses, with the remaining 1% to 4% being related to congenital causes.

The distributions of upper and lower extremity (LE) amputation by level are shown in Figure 74-1. In the LE, 75% to 93% of acquired amputations are the result of vascular disease (diabetic vascular disease, atherosclerosis, immunologic, and idiopathic). Diabetes alone contributes to two thirds of all LE amputations (2,3). Approximately 6% to 10% of acquired LE amputations result from traumatic injuries with the remainder due to benign or malignant tumors. While accounting for a smaller overall percentage of LE amputation, trauma is the most common cause for LE amputation in the second and third decades of life. Among those between the ages of 10 and 20 years, tumor is the most frequent cause of all amputations (4–6).

In the upper extremity (UE), trauma is the leading cause of limb loss, accounting for 80% of amputations with the vast majority of injuries limited to digital amputations. There are an estimated 10,000 to 15,000 upper limb amputations at the transradial level and above yearly in the United States (Table 74-1) (7). Most of these occur in individuals between the ages of 20 and 40 years. As in the LE, tumor is the most common cause of UE amputation in children.

From 1988 to 1996, the rates of trauma- and cancer-associated amputations declined by more than 40% (2,8). This decline likely reflects improved surgical reconstruction techniques for trauma, limb-sparing management of musculoskeletal tumors, and greater prevention through improved safety awareness. In contrast to the reduction in tumor- and trauma-related limb loss, dysvascular amputation rates have increased 10% to 19% over the past several decades. The increase in dysvascular-related amputation has occurred despite considerable evidence that comprehensive management of the diabetic foot at risk can substantially reduce or delay amputation. Factors that account for this adverse trend include the difficulty of implementing systematic comprehensive management strategies for the diabetic foot coupled with an increasing prevalence of diabetes, hypertension, and hypercholesterolemia placing more individuals at risk (2,9,10).

### Congenital Amputation

The absence of part or all of an extremity at birth is more appropriately referred to as a congenital skeletal deficiency rather than a congenital amputation. The Birth Defects

**FIGURE 74-1.** Percentage and level of amputations. (Data taken from the AHRQ and the VHA.)

Monitoring Program, a national program monitoring congenital malformations in the United States, reports the incidence of congenital upper and lower limb skeletal deficiency as 2.41/10,000 births (upper limb, 1.58/10,000 births; lower limb, 0.83/10,000 births) (11). Although a few genetically determined syndromes such as heart-hand malformation (Holt-Oram), renal dysfunction (Fanconi), thrombocytopenia (multiple named syndromes), absent radius and drugs (e.g., thalidomide) have

been associated with skeletal deficiencies (12–14), no etiology can be determined for most congenital limb loss.

Multiple systems for classifying congenital limb deficiencies have been proposed but none has been universally accepted. A commonly used and preferred system is based on the International Society for Prosthetics and Orthotics recommendations that classify congenital limb loss as either a transverse or longitudinal skeletal deficiency. Transverse limb deficiency, also referred to as terminal deficiency, is defined as the loss of all skeletal components distal to a particular transverse axis (e.g., transverse forearm or transverse radial limb deficiency). Longitudinal limb deficiency, also referred to as intercalary limb loss, is defined as the loss (complete or partial) of one or more skeletal elements within the longitudinal axis of the limb, with preservation of some or all of the distal skeletal elements. Classification of congenital limb deficiencies is often confused further when congenital deficiencies are described in the same terms used for acquired amputations, such as “transradial” or “transtibial.” Similar terminologies are used either because the congenital deficiency appears similar to an acquired amputation or because a congenital skeletal deficiency has undergone a surgical conversion to accommodate appropriate prosthetic restoration. Surgical conversion has been estimated to be necessary in the management of 50% of LE congenital deficiencies and 8% of UE deficiencies (15).

### Amputation Surgery

The underlying principle in choosing the amputation level is to preserve as much limb length as possible that will be consistent

**TABLE 74.1** Numbers and Adjusted Rates of Limb Loss by Etiology and Level (7)

Level	Dysvascular No. (%) 1988–1996	Trauma-Related No. (%) 1988–1996	Cancer-Related No. (%) 1988–1996
Lower limb (total)	953,367 (97)	61,605 (31)	8,351 (76.1)
Toe	309,589 (31.5)	27,233 (13.9)	1,466 (13.4)
Foot	102,872 (10.5)	4,483 (2.3)	482 (4.4)
Ankle	7,478 (0.8)	823 (0.4)	164 (1.5)
Transtibial	271,550 (27.6)	14,244 (7.3)	1,501 (13.7)
Through-knee	4,237 (0.4)	921 (0.5)	133 (1.2)
Transfemoral	253,145 (25.8)	10,821 (5.5)	2,499 (22.8)
Hip disarticulation	3,554 (0.4)	418 (0.2)	726 (6.6)
Pelvic	469 (0.1)	52 (0.03)	1,369 (12.5)
Bilateral	0 (0)	1,504 (0.8)	0 (0)
Upper limb (total)	29,426 (3)	134,421 (68.6)	2,617 (23.9)
Thumb	2,344 (0.2)	24,325 (12.4)	352 (3.2)
Finger(s)	21,427 (2.2)	100,316 (51.2)	529 (4.8)
Hand	1,255 (0.1)	983 (0.5)	92 (0.8)
Wrist	514 (0.1)	415 (0.2)	21 (0.2)
Transradial	1,626 (0.2)	4,001 (2.0)	212 (1.9)
Through-elbow	385 (0.04)	346 (0.2)	123 (1.1)
Transhumeral	1,511 (0.2)	3,008 (1.5)	488 (4.4)
Shoulder	236 (0.02)	154 (0.1)	365 (3.3)
Bilateral	0 (0)	462 (0.2)	0 (0)
Forequarter	132 (0.01)	15 (0.01)	439 (4)

with wound healing, an acceptable soft-tissue envelope, and functional prosthetic fitting. While in principle, decision making is straightforward, in practice many issues must be weighed including the severity of the underlying disease process, tissue viability, overall medical condition of the patient, the morbidity associated with limb salvage, expected functional level after amputation, and ultimately patient–physician preference. In patients with vascular disease, noninvasive vascular studies can assist in predicting wound healing; an absolute ankle Doppler blood pressure of 70 mm Hg or greater, an ankle-brachial index of 0.5 or greater, and transcutaneous oxygen pressure of greater than 20 to 30 mm Hg are all suggestive of a greater likelihood of healing at the transtibial level. Other nonvascular factors associated with compromised wound healing include poor nutritional status (albumin below 3.5 g/dL) or immunocompromised status (total lymphocyte count <1,500). Despite these identified predictive factors, the final choice of amputation level in the vascular patient often cannot be made until the time of surgery, when the amount of blood flow in the relevant tissues can be observed (8,16–18). In most medical centers, the physiatrist plays a limited role in presurgical planning. In centers where multidisciplinary teams are involved, the physiatrist can offer useful insights into the likelihood of achieving various functional goals at differing levels of amputation. This information allows the health care team and the patient to weigh surgical options when uncertainty exists.

The decision between amputation and limb salvage following trauma is a complex one. Early or immediate amputation may be required in life-threatening multiple trauma situations when the physiologic demands associated with repeated surgery to salvage a limb would not be tolerated. The presence of preexisting medical conditions such as peripheral vascular disease (PVD) or neurologic injury that adversely affect function of the residual limb may also favor immediate amputation. However, when the injuries are not immediately life-threatening, the decision to amputate versus attempting limb salvage must be based on an assessment of the approach that will most effectively restore function and return the individual to his or her preinjury activities. Extensive soft-tissue loss, proximal arterial injuries, multiple arterial injuries, and sciatic or tibial nerve damage are poor prognostic indicators for successful limb salvage (17,19). In general, limb salvage of the LE requires more surgeries, involves longer hospital stays, delays weight bearing, and slows the return to preinjury activities compared to amputation (19). Because the functional demands of the UE are different from the LE, a bias towards limb salvage has developed in UE trauma surgery. The lack of weight-bearing forces, the ability to function with partial sensation, and the limited functionality of UE prostheses are reasons cited for greater effort directed toward limb salvage and reimplantation (20,21).

Amputation surgery must be approached as a reconstructive procedure. Bones are beveled to minimize the sharp edges that can cause tissue trauma and pain with weight bearing. The nerves are sharply transected and allowed to retract into proximal soft tissues so that they do not become adherent in

scar or remain in a location subjected to high loading forces from a prosthesis. Appropriate myofascial closure of the muscle or myodesis provides for good control of the remaining bone in the residual limb, and appropriate placement of the skin incision line avoids bony prominences and adherence to underlying bone. Such attention to detail will result in a well-shaped residual limb that can be effectively fitted with a prosthesis. Ilizarov techniques or free fibular grafts (22–24) have been used to lengthen short residual limbs, though the indications for their use and their success are highly individualized. Skin grafts and myocutaneous free flaps (25,26) have been used successfully to preserve length in nonvascular individuals with an amputation, but in general the presence of skin grafts or insensate skin in the residual limb often results in recurring skin breakdown. When recurring skin breakdown occurs, stump revision, use of tissue expanders, and creative approaches to prosthetic design may be needed. The preferred levels of amputation are as follows.

### Lower Extremity

- Toe amputations
- Ray resections
- Transmetatarsal amputations
- Syme amputation (i.e., ankle disarticulation)
- Transtibial amputation (between the junction of the middle and distal thirds of the leg)
- Knee disarticulation (KD)
- Transfemoral amputation (8 cm or more proximal to the level of the knee joint)
- Hip disarticulation (short transfemoral amputation at/or proximal to the greater trochanter is functionally a hip disarticulation)
- Hemipelvectomy

### Upper Extremity

- Digital amputation
- Ray resection
- Transmetacarpal resection
- Wrist disarticulation (WD)
- Transradial amputation
- Elbow disarticulation
- Transhumeral amputation (THA) (i.e., 6.5 cm or more proximal to the elbow joint)
- Shoulder disarticulation
- Forequarter amputation (interscapulothoracic disarticulation)

## LE AMPUTATION

### General Principles of LE Amputation Management

The interaction between the health care team and the patient to achieve the goal of prosthetic restoration and rehabilitation is referred to as prosthetic management (27). The process of prosthetic rehabilitation can be organized into a four-phase

process: preprosthetic management, postoperative care, prosthetic fitting and training, and long-term follow-up care. This staging permits the rehabilitation physician to assess the individual with an amputation and organize the rehabilitation program.

### Preprosthetic Patient Evaluation and Management

Preprosthetic management begins when the decision to perform an amputation is made, when a patient is initially evaluated after a traumatic amputation, or when a child is born with a congenital skeletal deficiency. It ends with the fitting of a prosthesis. Optimal care is ensured when members of the prosthetic team can evaluate the patient before amputation, but often the events surrounding an amputation delay the rehabilitation assessment until the postoperative period.

The preprosthetic evaluation, whether performed preoperatively or postoperatively, should focus on identifying factors that will affect the ultimate functional status of the patient and optimize prosthetic fitting. Issues that need evaluation include assessing the premorbid functional status, identifying coexisting musculoskeletal, neurologic, and cardiopulmonary disease that will influence the rehabilitation potential, determining the available social support network, and understanding the patient's goals and expectations. Education of the patient and family about the functional consequences of amputation and the steps involved in prosthetic rehabilitation will help allay some of the fears the patient may have about his or her future. Therapy programs for range of motion, conditioning exercises, correct positioning of the residual limb, ambulation with gait aids, relaxation techniques, and activities of daily living (ADLs) should be started as soon as medically appropriate. The patient is often better able to absorb and comply with a therapy program during the preoperative period than during the early postoperative period, when incisional pain, medication, or apprehension may interfere with the ability to participate.

### Postoperative Care

The goals that direct the postoperative, preprosthetic management of the individual with an amputation are outlined in Table 74-2. During the immediate postoperative

period, general medical care focuses on optimizing control of underlying disorders that can interfere with rehabilitation: diabetes, coronary artery disease, congestive heart failure, renal disease. Maintaining nutritional status is frequently neglected, nevertheless it plays a critical role in ensuring wound healing (8) and in facilitating the muscular strength adaptations needed for prosthetic mobility. The principles guiding residual limb care are based on ensuring primary wound healing, controlling pain, minimizing edema, and preventing contractures.

Options for wound management include soft dressings, semi-rigid dressings (Unna casts), rigid dressings (plaster or fiberglass casts), and air splints. Each option has advantages and disadvantages. Soft dressings are typically used with an elastic bandage wrap (i.e., Ace bandage) or a compressive stockinette. Soft dressings have the advantage of being readily available, quickly applied, and allowing frequent wound inspection. However, they do not provide protection from external trauma and only have a limited ability to control edema. If poorly applied, elastic wraps can lead to tourniquet effect. Elastic bandages require considerable cooperation, skill, and attention on the part of the patient, family, and medical staff because the wraps need to be reapplied frequently and carefully to be successful. In practice their use is problematic enough and alternatives such as compressive stockinettes, elastic stump shrinkers, or roll-on gel liners are often a better choice of edema management. Despite a number of limitations, soft dressings remain the most commonly used wound care approach following amputation (28).

Rigid dressings have been reported to reduce wound-healing time and lead to more rapid and improved rehabilitation (29,30). The primary concerns surrounding rigid dressings are the inability to inspect the wound and the potential increase in wound breakdown from incorrect application or early weight bearing in dysvascular individuals with an amputation. In spite of these limitations, postoperative rigid dressings may be the preferred method of wound care, especially for the transtibial individual with an amputation, but their clinical use and acceptance has been limited by the lack of expertise in their application. Rigid dressings can be fabricated in a removable form that resembles a transtibial prosthetic socket or as a nonremovable cast that extends to the mid-thigh level. The rigid dressing is most commonly made using standard orthopedic cast materials but commercially available prefabricated devices are also available. A nonremovable rigid dressing is typically applied during or shortly after surgery and replaced every 7 to 14 days. The mid-thigh length of the dressing prevents knee flexion contractures and is continued until adequate wound healing has occurred so that concerns over contracture development are minimized. Subsequent dressings are fabricated as removable rigid dressings (RRDs) that can be taken off whenever the wound needs to be inspected. Rigid dressings have been predominantly used in the individuals with a traumatic amputation because of lessened concern over wound healing or limb injury from the dressing. While rigid dressings can be used simply as a wound care strategy, they can also be used with a pylon attachment to which components

**TABLE 74.2** Goals of Postoperative Management of the Individual with an Amputation

- Successful healing of the amputation
- Pain control
- Maintaining range of motion in the remaining proximal joints of the amputated extremity
- Strengthening of residual muscle groups needed for biomechanical compensation
- Preparation of the residual limb for prosthetic fitting
- Achieving independence in ADLs and mobility without a prosthetic limb
- Education about the process of prosthetic limb fitting and expected functional outcome
- Psychosocial support for the adaptations resulting from the amputation

can be attached, creating a preparatory prosthesis that enables immediate or early weight bearing.

Because little objective data exist that clearly identify a superior wound dressing strategy, the choice of wound management appears to be driven largely by practice conventions, availability of skilled staff, and the personal experience of the surgeon. Greater attention is needed to facilitate rapid wound healing, especially in the individual with a dysvascular amputation in whom the effects of prolonged immobilization may substantively complicate rehabilitation effects. The preprosthetic phase of management, before preparatory prosthetic fitting, can typically last 6 to 10 weeks for the individual with a dysvascular LE amputation, a considerably shorter period of time for the individual with a traumatic LE amputation, and 3 to 6 weeks for the individual with a UE amputation (12).

Muscle imbalance and postoperative positioning to facilitate comfort leads to the development of knee flexion contracture in the transtibial residual limb and to hip flexion and abduction contractures in the individual with a transfemoral amputation. Contractures are preventable through a postoperative therapy program that emphasizes range of motion exercises and early mobilization. Strengthening of muscle groups that biomechanically substitute for the lost function of the limb is needed. Exercise programs are required to accomplish this task. In the individual with a LE amputation, the hip extensors (gluteus maximus and hamstrings), gluteus medius, hip flexors, and the contralateral ankle plantar flexors all contribute to restoring ambulation ability (31,32). In the individual with a UE amputation, proximal shoulder girdle muscle strengthening should be taught, emphasizing the trapezius, serratus anterior, pectoralis major, as well as any residual deltoid and biceps functions.

An individual's psychological response to amputation may be compared to the grieving process that variably includes identifiable stages of denial, anger, depression, coping, and acceptance. Not every person ultimately adapts to limb loss. The individual's ultimate response to the psychosocial impact of limb loss is determined by many factors, including the cause of amputation, personal life experience and inner strengths, the available social support system, the care provided by the prosthetic team, and the functional outcome that is achieved through rehabilitation.

### Prosthetic Fitting and Training

An understanding of the functional needs of the individual with an amputation, his/her interest and motivation in pursuing prosthetic fitting, and an assessment of his/her ambulatory potential are required to set realistic goals for prosthetic fitting and training. Not all the individuals with an amputation are candidates for prostheses. Although the factors that predict success in prosthetic use are partially understood, a number of factors have been associated with a poor outcome in returning the individual with an amputation to functional ambulation at household or community levels. Negative prognostic factors include a delay in wound healing, the presence of joint contractures, dementia or cognitive disorders, medical comorbidities,

and higher levels of limb amputation (transfemoral) (33–35). Age has inconsistently been identified as a predictor of prosthetic success, implying that except in advanced age (>80 to 85 years) other factors play a more important role in determining the rehabilitation potential of the individual with an amputation.

As a result of the uncertainty in identifying prosthetic candidates, considerable clinical judgment is required. Some general guidelines can be followed. An individual with an amputation should have reasonable cardiovascular reserve, adequate wound healing, and good soft-tissue coverage, range of motion, muscle strength, motor control, and learning ability to achieve useful prosthetic function. Individuals with an LE amputation who can walk with a walker or crutches without a prosthesis usually possess the necessary balance, strength, and cardiovascular reserve to walk with a prosthesis. Examples of poor candidates for functional prosthetic fitting would be an individual with a dysvascular LE amputation with an open or poorly healed incision, an individual with a transfemoral amputation with a 30-degree flexion contracture at the hip, or an individual with a transradial amputation with a flail elbow and shoulder. Generally, individuals with a bilateral, short, transfemoral amputation over the age of 45 years are considered unlikely candidates for full-length prosthetic fitting. Additional medical problems such as severe coronary artery disease, pulmonary disease, severe polyneuropathy, or multiple-joint arthritis may result in an individual with an amputation who could be fitted with a prosthesis but who may not be a functional prosthetic user. Patients in whom prognosis is poor, life expectancy is short, or with a disease that results in significant fluctuations in body weight are not good candidates. In borderline cases, it may be necessary to proceed with actual prosthetic fitting to determine the eventual prosthetic function. The use of a less costly, RRD with pylon and foot or a preparatory prosthesis is appropriate before a decision is made about fitting such a person with a more costly definitive prosthesis. The overall success rate in restoring functional ambulation in the individual with a lower limb amputation varies approximately from 36% to 70%. Amputation resulting from vascular disease is a manifestation of a severe systemic vasculopathy. The early mortality following major LE amputation is 15% to 20%, largely related to myocardial infarction. Overall, the individuals with dysvascular amputation have a 3- to 5-year 50% mortality, which underlies the importance of successful early rehabilitation to allow for an improved quality of life in their remaining years.

The timing of prosthetic fitting for the individual with an LE amputation remains controversial, reflecting the clinical uncertainty over early versus delayed weight bearing. Because the majority of LE amputations occur as a result of PVD, primary wound healing at the amputation site is of paramount importance. When the rigid dressing was introduced on a wide scale in the 1970s, it was used to implement immediate postoperative prosthesis (IPOP) (a rigid dressing with a pylon and foot) as a means to speed rehabilitation for individuals with LE amputation (36). Problems with wound healing and

residual limb trauma from poorly fabricated devices and a lack of experienced teams to manage this approach to early postoperative care led to abandoning their use in the individual with a dysvascular amputation. Despite these problems, in selected centers with adequate experience and a process to monitor closely the residual limb, an immediate or early postoperative prosthesis fabricated several weeks after surgery has been used safely in individuals with a dysvascular amputation (37). Immediate fitting in the younger patient with traumatic amputation has been more successful and is a reasonable method of treatment. Immediate and early postoperative prostheses are, in effect, an RRD with a pylon and foot attached. This device is used to achieve limited partial to full weight bearing, reduce edema, and accomplish initial gait training. Because the fit of these devices is always suboptimal compared to a custom-molded socket, they are not recommended for extended use.

When concern over wound healing dominates clinical care in the postoperative period, prosthetic fitting is delayed until the residual limb has healed adequately to allow unrestricted weight bearing. Providing a prosthesis is typically performed in two stages: a preparatory prosthetic limb phase is followed by the provision of a definitive prosthesis. The preparatory prosthesis is often of simple design, lower performance, and is more accommodating to changes in residual limb volume than is the definitive limb. It allows the individual with an amputation to gain skill and confidence in walking with prosthesis, facilitates residual limb maturation, and affords the rehabilitation team the opportunity to better define the ultimate functional level of the individual. When stump maturation has occurred, a definitive prosthesis is prescribed to meet the anticipated needs of the individual with an amputation.

Stump maturation is an imprecisely defined concept that occurs when the volume of the residual limb has stabilized, soft-tissue atrophy has occurred, and the residual limb has been molded into a cylindrical shape that optimizes prosthetic fitting. This can usually be determined when the individual with an amputation reports a plateau in the number of sock plies worn from day to day and by clinical exam that shows edema resolution. Residual limb maturation, typically, takes about 4 months (38) but may extend substantially longer depending on the activity level, amount of prosthetic limb use, and coexisting medical disease. After stump maturation occurs, a definitive prosthesis is prescribed to specifically meet the ADLs and vocational and avocational needs of the individual with an amputation. In the case of young children, the prosthesis prescription must also meet any needs related to the development of age-appropriate motor milestones. Although a two-stage approach (preparatory followed by definite limb) is commonly used, financial considerations are becoming increasingly important with many health insurance programs allowing for only a single limb. Under these situations, the prosthetic team may recommend as the initial prosthesis a limb that is projected to meet all the long-term needs of the individual with an amputation. Patients who are not candidates for functional prosthetic use may choose to have a cosmetic prosthesis that has an appearance similar to that of the opposite limb.

## Gait Training

After completing the final prosthetic evaluation, the individual with a new amputation will require a period of gait training under the supervision of the physical therapist. The individual with an amputation is instructed on how to put on and take off the prosthesis, how to determine the appropriate number of limb socks to be worn, when and how to check the skin for evidence of irritation, and how to clean and care for the prosthesis. For the individual with a new amputation it is best if the initial gait training occurs while the prosthesis is still capable of being adjusted to permit alignment or length changes that may become apparent during gait training. Gait training often occurs on an outpatient basis and may last from weeks to months. The more proximal levels of amputation require lengthier gait training.

Gait training begins with weight shifting and balance activities while still in the parallel bars. Once weight shifting and balance activities have been mastered, a program of progressive ambulation begins in the parallel bars and progresses to the most independent level of ambulation possible with or without gait aids. Specific training should focus on transfers, knee stability, equal step lengths, and avoiding lateral trunk bending. Following mastery of ambulation on flat, level surfaces, techniques for managing uneven terrain, stairs, ramps, curbs, and falling and getting up off the ground are learned. Moving from a walker to less cumbersome gait aids can be achieved for most individuals with an LE amputation. For higher functioning individuals with an amputation, prosthetic training should include instruction and practice in driving, recreation, and vocational pursuits. Developing the optimal benefit from a prosthesis must take into account the specific mechanical attributes of the components used. For example, using a dynamic response (i.e., energy-storing) prosthetic foot requires loading the prosthetic toe during mid-stance and late stance to capture energy for push off assistance or to activate a prosthetic knee to initiate the swing phase.

Wearing tolerance for the prosthesis must be gradually increased. Initially, the individual with an amputation will wear the prosthesis only for 15 to 20 minutes, removing it to check the condition of the skin. As tolerance to weight bearing increases, the length of wearing time is gradually increased. Several weeks may be required before the individual with an amputation is able to wear the prosthesis full-time. The individual with an amputation may take the prosthesis home when safe and independent ambulation has been demonstrated and residual limb skin checks are assured. Common gait deviations and their causes are highlighted in Table 74-3.

## LE Prosthetic Follow-up

During the initial 6 to 18 months, most individuals with an amputation will experience continued loss of residual limb volume, resulting in a prosthetic socket that will be too large. During this period, return visits should occur frequently enough to ensure that this loss of residual limb volume is being compensated for by the use of additional limb socks or by appropriate modifications of the prosthetic socket. It is usual for an individual with a new amputation to require replacement of the

**TABLE 74.3** Abnormalities of Amputee's Gait

Transtibial Amputee Gait			
Gait Cycle	Observed Gait Abnormality	Possible Cause	Suggested Modifications
Initial contact to loading response	Abrupt heel contact, rapid knee flexion	Excessive heel lever <sup>a</sup>	Realign prosthetic foot, change heel stiffness
	Prolonged heel contact, knee remains fully extended	Inadequate heel lever <sup>b</sup> or heel worn out	Increase heel stiffness
	Jerky knee motion	Improper socket flexion Learned gait pattern, quadriceps weakness Socket loose, poor alignment, inadequate suspension	Realign prosthesis Gait training and strengthening
Mid-stance	Medial or lateral socket thrust, lateral trunk shift over prosthesis	Foot too far outset or inset, socket loose	Realign prosthesis, replace socket or adjust socks
Mid-stance to terminal stance	Pelvis drops or elevates	Prosthesis too short/too long	Adjust prosthetic length
	Early knee flexion or "drop off"	Inadequate toe lever <sup>c</sup>	Realign prosthesis, replace foot
Terminal stance	Heel off too early	Excessive toe lever <sup>d</sup> , too much socket extension	Realign prosthesis
	Heel off excessively delayed	Inadequate toe lever <sup>c</sup> , too much socket flexion	Realign prosthesis
Swing phase	Prosthetic foot drags	Prosthesis too long, inadequate suspension	Shorten limb, modify suspension
Successive double support	Uneven step length	Hip flexion contracture, gait insecurity Uncomfortable socket	Physical therapy Adjust socket fit
Transfemoral Amputee Gait			
Initial contact to loading response	Foot rotation at heel strike	Poor socket fit/rotation	Adjust socket fit, add belt for rotation control
	Knee buckling	Heel too firm Excessive heel lever <sup>a</sup> Incorrect prosthetic knee alignment Weak hip extensors	Reduce heel stiffness Realign limb, reduce heel stiffness Realign TKA relationship Gait training and strengthening
Mid-stance	Lateral trunk bend or shift over prosthesis	Prosthetic limb abducted	
		Too much socket abduction, foot too far outset	Realign prosthesis
		Prosthesis too long	Shorten prosthesis
		Medial groin pain	Adjust socket fit
		Poor medial-lateral prosthetic control	
Initial swing	Uneven heel rise	Poor socket fit	Adjust socket fit
		Weak hip abductors	Gait training and strengthening
		Short residual limb	Accept, possibly add hip joint
		Prosthesis too short	Adjust prosthetic length
Swing phase	Circumduction or prosthetic limb	Knee friction too tight or loose	Adjust knee friction or damping
		Knee extension	Adjust knee friction or damping
		Inadequate knee flexion, knee too stiff	Adjust knee friction or damping
Successive double support	Whips Uneven step length	Prosthesis too long, inadequate suspension	Adjust prosthesis length
		Poor gait pattern	Physical therapy
		Improper knee rotational alignment	Realign prosthesis
		Excessive socket rotation	Adjust socket fit
		Hip flexion contracture	Physical therapy
		Insufficient socket flexion	Realign prosthesis

<sup>a</sup>Causes of excessive heel lever—foot dorsiflexed too much, foot too far posterior, heel cushion too hard, shoe heel too hard.<sup>b</sup>Causes of inadequate heel lever—foot plantarflexed too much, foot too far anterior, heel cushion too soft.<sup>c</sup>Causes of inadequate toe lever—foot dorsiflexed too much, foot too far posterior, foot keel too soft/flexible.<sup>d</sup>Causes of excessive toe lever—foot plantar flexed too much, foot too far anterior, foot keel too stiff.

**TABLE 74.4 Medicare Guidelines for Functional Classification of Patients with Prosthesis**

K Code Level	Functional Level	Activity Level
K0	Not a potential user for ambulation or transfer	Does not have the ability or potential to ambulate or transfer safely with or without assistance, and a prosthesis does not enhance their quality of life or mobility.
K1	A potential household ambulator including transfers	Has the ability or potential to use a prosthesis for transfer or ambulation on level surfaces at fixed cadence. Typical of the limited and unlimited household ambulator.
K2	A potential limited community ambulatory	Has the ability or potential for ambulation with the ability to traverse low level environmental barriers such as curbs, stairs or uneven surfaces. Typical of the limited community ambulator
K3	Community ambulator using variable cadence, including therapeutic exercise or vocation	Has the ability or potential for ambulation with variable cadence. Typical of the community ambulator that has the ability to traverse most environmental barriers and may have vocation, therapeutic, or exercise activity that demands prosthetic utilization beyond simple locomotion.
K4	High activity user which exceeds normal ambulation skills	Has the ability or potential for ambulation that exceeds basic ambulation skills, exhibiting high impact, stress, or energy levels. Typical of the prosthetic demands of the child, active adult, or athlete.

prosthetic socket during this time because of the significant loss of soft-tissue volume. During follow-up visits, the condition of the residual limb, the prosthesis, the individual's gait, and the level of function are reviewed (39). Appropriate medical treatment, prosthetic modifications, or additional therapies are prescribed as needed. When the residual limb volume has stabilized sufficiently and the patient is doing well with the prosthesis, yearly visits to the amputee clinic are appropriate. Once the residual limb has stabilized, the average life expectancy for an LE prosthesis before replacement should be 3 to 5 years.

### LE Prostheses

The LE prosthetic prescription must balance the individual's need for stability, mobility, durability, and cosmesis with available resources and cost. Understanding the role and importance of prosthetic ambulation in achieving the mobility goals of the individual with an amputation is essential for correctly prescribing a prosthetic device. Prosthetic ambulation is usually the primary mode of mobility for the younger individual with an amputation as well as for other patients across a wider age range when the amputation is at the transtibial and more distal levels. For the elderly, with dysvascular amputation above the knee and a more proximal level of amputation, prosthetic ambulation is often limited to transfers, indoors, or short community distances. The prescription of the LE prosthesis is based on several principles: maximizing comfort, matching specific components to the mobility needs of the individual with an amputation, and providing acceptable cosmesis. Comfort is the most critical aspect and depends on achieving an appropriate distribution of forces between the residual limb and the socket. A poorly fitting or uncomfortable socket will limit the mobility and often lead to rejection of the prosthesis. Once comfort has been established, the appropriate choice of components facilitates achieving maximal independence and function during sitting, standing, transferring, walking, and running.

Lastly, cosmetic concerns are considered. Cosmesis is influenced by personal preferences and psychosocial dynamics but is usually satisfactorily achieved using contoured foam and a nylon or rubber skin tone cover. Some individuals with an amputation prefer not to have their prosthesis covered because of the possible interference with prosthetic component function.

Medicare, a major funding source for prosthetic limbs in the United States, requires that the functional level of the individual with an amputation be taken into account when prescribing a prosthesis. The functional index is referred to as the Medicare "K" code and limits the components that can be used when fabricating the prosthesis. Although only required for Medicare, the "K" code classification is a simple but useful hierarchical framework for classifying the mobility potential of all individuals with an LE amputation (Table 74-4).

### LE Prosthetic Components

The continual introduction of new component designs and the overlap of functional features of components from various manufacturers make it difficult to stay abreast of available prosthetic options. Collaboration between health care providers (physician, prosthetist, and therapist) is essential in developing an appropriate, individualized limb prescription. Seldom is there a single correct choice of components for a prosthesis, rather most individuals with an amputation can be successfully fit using components that span a reasonable range of mechanical and functional characteristics. Because objective data, linking prosthetic component characteristics to the demographics of individuals with an amputation, are limited, empiric approaches and experience play a major role in limb prescription. The prescription for an LE prosthesis should include the Medicare "K" code, diagnosis, type of prosthesis (with modifiers), socket type, liner, suspension method, foot, knee and hip systems (as required by amputation level), diagnostic or check socket, and supplies.

### Prosthetic Feet

Prostheses for amputations at or proximal to the ankle require the use of a prosthetic foot. The selection of an appropriate prosthetic foot is complicated by the wide range of foot designs, marketing-driven claims of performance, and the limited availability of objective data comparing the relative biomechanical and functional advantages of different feet. In the clinical setting, the selection of a prosthetic foot is largely empirically based on the conceptual goal of matching the functional characteristics of the foot to the expected activity needs of the individual (40–45). Within this approach, it is useful to group feet by their major functional feature(s) as belonging to rigid keel, flexible keel, single/multiaxial, or dynamic response (or energy-storing) categories. It is acceptable for the prescribing physician to define the functional features desired in the foot and to rely on the prosthetist who typically has a better working understanding of the commercially available feet to select the specific manufacturer and foot within the desired functional class. This multidisciplinary approach is increasingly important as foot designs become more sophisticated, more costly, and combine different functional characteristics into a single foot. Occasionally, another characteristic of a foot such as an adjustable heel height, cosmesis, or being waterproof is the primary determinate in its selection.

The solid ankle cushion heel (SACH) foot (Fig. 74-2) is the least expensive and most commonly prescribed prosthetic foot. It is durable and lightweight, which accounts in part for its usefulness. The SACH foot has no moving parts and consists

of a wooden or composite keel with a compressible foam heel and toes that flex under load, allowing limited simulation of the effects of the heel and forefoot rocker mechanisms of the normal foot. A SACH foot is appropriate for individuals with an amputation who have a lower activity level (K1 to K2), with ambulation primarily limited to level surfaces. It can be used in a wide range of individuals with an amputation for the preparatory prosthesis and upgraded as the individual with an amputation progresses to a higher activity level. For a juvenile with an amputation, the SACH foot is often the most cost-effective foot due to the need for frequent foot changes because of rapid growth.

The flexible keel foot (see Fig. 74-2) is designed to mimic the motion of the forefoot rocker mechanism by replacing the rigid keel of the SACH foot with a flexible keel. The keel bends with controlled stiffness as the foot moves from mid-stance through preswing. Several versions of flexible keel feet are commercially available, each with different construction but sharing similar function. The stationary-ankle-flexible endoskeletal (SAFE) II foot is a commonly used flexible keel foot. The flexible keel foot allows some inversion and eversion, and gives a smoother rollover than a SACH foot, making it appropriate for general mobility needs in the individual with an amputation with a low to moderate activity level. However, the more active individual with an amputation may perceive the flexible keel foot as being too soft, especially for fast walking or running activities.

Articulating prosthetic feet include both single axis and multiaxis designs. The single axis foot allows controlled movement in the sagittal plane (plantar-flexion and dorsiflexion), adjusted by using different durometer bumpers. The primary advantage of the single axis foot is its ability to reduce knee-bending movements during limb loading, thus improving knee stability. Disadvantages include a greater weight than many other feet and more maintenance to ensure correct function. This foot is primarily used in the individual with a proximal amputation that requires better knee stabilization, such as the elderly individual with a transfemoral amputation or the individual with a transfemoral amputation and a short residual limb.

Multiaxial foot designs allow for varying degrees of controlled movement in the sagittal, coronal, and transverse planes (plantar/dorsiflexion, inversion/eversion, some degree of transverse rotation). Multiaxis feet can use mechanical joints to supply motion such as the Greisinger foot or the College Park foot (see Fig. 74-2), but increasingly rely on the inherent flexibility of rubber and polymer materials to provide multiaxial motion. Using material flexibility improves durability and reduces both weight and maintenance compared to mechanical jointed feet. Multiaxis “ankle” motion can be integrated into the foot (e.g., Endolite foot, Luxon) or added to other feet through the use of separate multiaxial ankle components (e.g., impulse ankle—Ohio Willow Wood, Mt. Sterling, Ohio). Multiaxis capabilities are appropriate for the individual with an amputation who needs improved ankle motion to accommodate to uneven terrain and for the active individual with an amputation who requires greater ankle movement to adjust to different speeds or for cutting and pivoting quickly.

**FIGURE 74-2.** Prosthetic feet from the solid ankle cushion heel (SACH) and stationary attachment flexible endoskeletal (safe II flexible keel) foot (**top**). The impulse foot (dynamic response) and Luxon Max (dynamic response with multiaxis) (**middle**). The College Park TruStep (dynamic response, with some inversion, eversion, and transverse motion), the FlexFoot VSP (vertical shock pylon, dynamic response, multiaxis), and the Ceterus (VSP, dynamic response, multiaxis, and transverse motion) (**bottom**). The prosthetic manufactures have numerous feet available from the homebound to the paralympic patient. (Courtesy of Kingsley, Ohio Willow Wood, Otto Bock, CPI, OSSUR and Freedom Innovations. See prosthetic manufacture WEB Site Listings.)

Dynamic response (i.e., energy-storing) prosthetic feet incorporate elastic (spring-like) elements that store energy in the foot during limb loading and mid-stance as the elastic material compresses or flexes. Energy is returned at the time of push-off as the spring components of the foot returns to its normal shape or configuration. Examples include the Flex-foot, the Springlite feet, Seattle foot, and the impulse foot (see Fig. 74-2). The dynamic energy characteristics of these feet make them particularly suitable for individuals with an amputation involved in activities requiring running and jumping. Many individuals with an amputation believe that they are more functional with a dynamic response foot. Dynamic elastic response (DER) feet were expected to make ambulation more efficient by reducing the oxygen consumption of individuals with an amputation but the results of objective studies have been mixed (44,46). The metabolic benefits of DER designs are limited and primarily seen at faster walking speeds.

## Prosthesis by Level of Amputation

### Partial Foot Amputation

Toe amputations, ray resections, and transmetatarsal amputations require minimal prosthetic/orthotic intervention. At the more distal foot amputation levels and for the less active individual with a transmetatarsal amputation, accommodative shoes with custom insoles, arch supports, and toe fillers are usually adequate. More active individuals with a transmetatarsal amputation may benefit from orthotic modifications that better substitute for the lost anterior foot lever arm. Options include the addition of carbon fiber or spring steel sole shanks, rocker soles, or short ankle foot orthosis. Partial foot amputations at the tarsal-metatarsal and transtarsal levels (e.g., Lisfranc, Chopart) are relatively uncommon and have historically been associated with equinovarus contracture of the hind foot, increasing the likelihood of skin breakdown over the plantar surface of the foot. However, improved surgical techniques that include Achilles tendon lengthening/resection and anterior tibialis and peroneus tendon transfers have reduced equinovarus deformities and result in a functional and useful amputation level (47,48). Prosthetic/orthotic devices for the individual with a proximal partial foot amputation need to supply medial-lateral stabilization of the hind foot and substitute for the lost forefoot lever. Options include: (a) an extra-depth shoe with toe filler, steel shank, and rocker bottom modifications; (b) custom posterior leaf-spring ankle-foot orthosis with toe filler; or (c) a custom prosthetic foot with a self-suspending rear-opening split socket (47,48). A major advantage of all partial foot amputations is the ability to be fully end-bearing, allowing ambulation without any devices.

### Syme Amputation

Similar to the hind foot amputation, the Syme (tibiotarsal disarticulation) amputation is capable of full weight end bearing. The heel flap is anchored to the distal end of the tibia and fibula, and following healing, allows short distance ambulation without a prosthesis. The substantial leg length discrepancy makes long distance ambulation impractical. Over

**FIGURE 74-3.** From **left to right**: The posterior opening Syme for bulbous distal end; PTB Syme with Pelite liner; Canadian-type Syme prosthesis as modified by the Veterans Administration Prosthetic Center. (Courtesy of PSL Fabrication, Fulton, MO.)

time, posterior migration of the distal heel pad occurs in some individuals with a Syme amputation leading to problems with skin breakdown and difficulty in prosthetic fitting (49–51). The relatively bulbous distal end of the residual limb has the advantage of enabling the use of self-suspending prosthetic designs; however, it also contributes to the major disadvantage of the Syme amputation—poor cosmesis due to the bulkiness of the prosthesis around the ankle joint. There are several different types of prostheses available for individuals with a Syme amputation.

The most common prosthetic style uses a total contact socket with a removable medial window (Fig. 74-3). The distal removable medial window allows the bulbous portion of the residual to slip easily into the socket, which is then held in place by closing and securing the window with Velcro straps. The major disadvantages to this prosthesis style are the poor cosmesis and the reduced strength of the socket due to the window. A second option uses a fixed posterior opening socket. This type of prosthesis is used for a very bulbous residual limb. This prosthesis is prone to breakage at the ankle joint and is not recommended for heavy-duty users.

Alternative designs to window sockets use a flexible socket wall or liner to allow donning the prosthesis around the distal bulbous end of the residual limb. In the “stovepipe” design, a pelite or similar liner is used that is built proximal to the ankle area, creating a cylindrical stovepipe-shaped inner liner. To don the prosthesis, the patient slips the distal bulbous residual past the narrow center of the liner that can then be easily inserted into the socket. This style of prosthesis is somewhat bulky but can be easily modified and is durable, making it suitable for use as a preparatory prosthesis or in active or obese patients.

The expandable wall prosthesis uses a double-wall socket that has a flexible, expandable inside liner and a rigid outer frame. The inner wall is made of silicone or other elastomers that are flexible enough to allow the bulbous residual limb to slide into the prosthesis. This prosthesis is typically difficult to modify but has the advantage of being very strong and useful for active users or obese patients, and is generally easy to don and doff, making it suitable for individuals with upper limb impairment or cognitive impairment.

**FIGURE 74-4.** Areas that are pressure intolerant and tolerant for modification and fabrication of a specific weight-bearing (SWB) or PTB socket.

Low-profile feet are needed for Syme prosthesis due to the limited space available beneath the socket. Acceptable foot options range from the rigid keel SACH feet through multi-axial and dynamic response feet.

### Transtibial Amputation

Transtibial amputations are the most common amputation level seen in general practice. Considerable effort over the past several decades has gone into designing components to address the needs of individuals with transtibial amputations. The large number of options available increases the uncertainty when choosing components but if approached systematically, straightforward reasoned decisions can be used to generate a prosthetic prescription. The following discussion of transtibial prosthetic components parallels the recommended approach for prescribing prostheses. Initially, the socket and liner system that is anticipated to optimize comfort and skin protection is

determined. Next, the suspension system is chosen and finally pylon and foot/ankle components are selected.

The patella tendon-bearing (PTB) total contact socket has been the internationally accepted standard transtibial socket since the 1960s (52). The PTB total contact socket is fabricated from a cast of the residual limb which is modified to specific weight bearing (SWB) regions that are pressure tolerant and correspondingly modified to decrease pressure over bony prominences such as the tibia crest, fibula, and distal portion of the tibia (Fig. 74-4).

The standard PTB design has several variations (53–55). The PTB-Supracondylar (PTBSC) socket has high medial and lateral sidewalls that extend above and over the femoral condyles, providing enhanced mediolateral stability and self-suspension of the prosthesis. The PTB-Supracondylar/suprapatellar (PTBSCSP) socket further extends the PTBSC socket concept by also extending the anterior aspect of the socket so that the patella is encompassed within the socket. The PTBSCSP gives additional stiffness to the mediolateral walls and applies force proximal to the patella during stance to provide sensory feedback to limit genu recurvatum. Both the PTBSC and PTBSCSP are primarily used in individuals with an amputation and with short residual limbs to improve varus/valgus control and to provide greater surface area for weight distribution (Fig. 74-5).

An alternative socket design for individuals with a transtibial amputation is the total surface-bearing (TSB) socket made practical by the development of gel and elastomeric liner systems (discussed below). The TSB socket is made from a cast of the residual limb with minimal modifications. When used with gel liners, the TSB socket is believed to distribute pressure more uniformly within the socket. The relative advantages and disadvantages of TSB versus PTB total contact sockets remain poorly understood. When a comfortable fit cannot be achieved with one type of socket, empirically switching to the other can be successful.

**FIGURE 74-5.** PTB style sockets (SWB).

Socket fit coupled with the choice of a liner are key considerations in assuring comfort and acceptance of the prosthetic limb. The liner functions as the primary interface between the residual limb and the remainder of the prosthesis. In this role, it must complement socket fit to ensure optimal pressure distribution while also eliminating harmful shear forces and providing a favorable moisture, heat, and chemical environment that prevents skin breakdown. PTB total contact sockets can be fit as hard sockets that do not use a liner or more commonly use a liner made from closed cell foam such as Pe-Lite for improved comfort. Using PTB total contact sockets and pelite liners are often an advantage in the preparatory prosthesis because of the relative ease with which the liner can be modified to accommodate changes in residual limb volume (52,55,56). Roll-on silicone or elastomeric gel liners are another option that can be used with a PTB total contact socket but are generally recommended for use with TSB socket designs. Gel liners are thought to enhance comfort and reduce shear, making them the initial choice for residual limbs with scarring or skin grafts that compromise skin integrity (52,56). Gel liners result in more sweating and are generally less tolerated in warm climates than other liners. Contraindications to the use of gel liners are residual limbs with open wounds, poor hygiene, or a history of contact dermatitis.

The suspension system for the transtibial prosthesis must securely attach the limb during activities, minimize pistoning, and be comfortable when sitting. When working with individuals with an amputation who run, play sports, or are involved in climbing activities, ensuring effective suspension is especially important. Suspension systems can be grouped into categories that include straps, sleeves, gel liners with locking mechanisms, and suction (Fig. 74-6). A commonly used suspension system is the supracondylar cuff strap. Several variants exist, all of which consist of a multipart strap that attaches to the sidewalls of the socket and encircles the distal thigh using the normal anatomic flare of the supracondylar portion of the femur to maintain suspension. The supracondylar strap is inexpensive,

easily applied, and is comfortable during sitting. It supplies adequate suspension for the low-to-moderate activity-level individual with an amputation and is often the best option when impaired hand function limits grip strength and coordination. Waist belts with an anterior fork strap that attaches to the socket are a rarely used suspension option. This type of suspension is most commonly used in conjunction with a PTB total contact socket with side joint and a high corset. The weight and bulk of the resulting limb makes it a poor initial choice for a contemporary prosthetic limb, but it does remain a useful option for long-term users of this design of prosthesis. Other individuals with an amputation who may benefit from this type of limb are those with a short transtibial amputation who require maximal medial-lateral stability for outdoor or work activities. This type of limb may also be preferred when coexisting ligamentous instability of the knee is present, or to partially off load a painful or weight-intolerant residual limb.

Sleeve suspension systems consist of rubber, neoprene, or elastic sleeves that are pulled up onto the distal thigh after donning the prosthesis (56). Sleeves are a general purpose suspension system that is inexpensive and effective for individuals with an amputation across a wide spectrum of activity levels. The primary disadvantages are related to excessive heat or sweating, the need for good grip strength to pull the sleeve up, and the occasional occurrence of contact dermatitis, especially with the use of neoprene-based sleeves. Silicone and elastomeric gel liners are prosthetic sock-shaped sleeves made from a variety of silicone and urethane elastomeric compounds that are rolled onto the residual limb. They function as both an interface and suspension method. The suspension function requires either a metal pin attached to the distal end of the liner which inserts into a locking mechanism in the bottom of the socket or by a Velcro lanyard strap that passes through a slot in the socket and connects with its counterpart attached to the outside of the socket. The suspension pin or lanyard securely anchors the liner to the socket, and the subsequent friction and suction that develops between the liner and the residual

**FIGURE 74-6.** Suspension systems used for the transtibial prosthesis.

**FIGURE 74-7.** TSB socket with gel liner and pin system, and custom-fabricated liners to accommodate any irregularities of the residual limb. If pin or lanyard system is not being used then the socket will be held by a suspension sleeve. (Courtesy of Otto Bock and Evolution Liners, see Web site listing.)

limb supplies the force required for suspension (Fig. 74-7). This approach provides excellent suspension for a wide range of activities and is increasingly being used as a general purpose suspension system. The main disadvantages of gel liners are their high cost compared to straps or sleeves and their limited durability, which necessitates replacement of the liners every 6 to 12 months. In the presence of loose or excessive soft tissue in the residual limb, elongation and stretching of the distal tissues during swing phase can occur that may lead to pain.

The last option for suspension of the transtibial prosthesis uses suction. By combining a one-way air valve ported to the bottom of the socket with an airtight sleeve a partial vacuum is created within the socket effectively suspending the prosthesis during the swing phase (57). The vacuum needed to hold the residual limb can be generated through a pistoning action of the residual limb within the socket or by a vacuum pump built into the prosthetic shank that is activated at heel strike or by an electric operated vacuum pump attached to the socket. These later options are known as vacuum-assisted socket suspension (VASS) (Fig. 74-8).

**FIGURE 74-8.** VASS works by use of a vertical shock pylon that acts like a vacuum pump and continually withdraws air from the sealed socket while ambulating. (Courtesy of Otto Bock, see Web site listing.)

Most contemporary prostheses are endoskeletal in design. Using an endoskeletal pylon allows alignment changes after prosthetic fabrication and enables the use of additional components that can absorb forces or allow motion between the socket and the remainder of residual limb. Commonly used components include transverse rotators that reduce axial torques and vertical shock absorbers that cushion impact loading and may reduce oxygen consumption (46,58). The selection of a prosthetic foot completes the transtibial prosthesis prescription.

### Knee Disarticulation

Knee disarticulations (KD) amputations share some of the same advantages and disadvantages as the Syme amputation (ankle disarticulation) (59). Similar to the Syme amputation, full weight bearing on the distal end of the KD residual limb is usually possible and the anatomic flare of the femoral condyles can be used for self-suspension of the prosthesis. Because of the improved distal weight bearing, the KD amputation does not require an ischial weight-bearing socket leading to enhanced comfort and sitting tolerance as does a transfemoral amputation. The KD has a bulbous distal end, which compromises prosthetic cosmesis. Compared to the individual with a transfemoral amputation, the long length of the KD residual improves the prosthetic control and allows a greater degree of dynamic muscular stability. However, the long residual limb limits the choice of prosthetic knee units that can be used to maintain symmetric knee centers between the amputated and nonamputated side. Advances in the design and development of the four-bar linkage or polycentric knee units (Fig. 74-9) offer good biomechanical function and acceptable limb cosmesis. KD, while an uncommon amputation level, is reemerging as an alternative to the transfemoral amputation when wound healing concerns are acceptable because of the improved sitting balance, reduced energy cost of walking, and better acceptance rate than that for a transfemoral amputation (60).

### Transfemoral Amputation

The development of new technology, materials, and prosthetic components over the past decade has arguably had the greatest impact on the care of the individual with an amputation at the transfemoral level. The following discussion of transfemoral prosthetic components is organized to parallel a reasonable approach to prescribing a prosthesis. Initially, the socket style is specified. Next the residual limb interface/liner and suspension system are determined. Because liner and suspension options are closely linked at the transfemoral level, they are discussed together. Following selection of socket and suspension, the knee unit is selected and finally pylon and foot/ankle components are chosen.

The quadrilateral socket introduced following World War II had been the standard socket design for transfemoral prostheses until the emergence of a new socket design, the ischial containment socket (ICS) during the past 15 years. The quadrilateral socket, named for its quadrilateral shape as viewed in the transverse plane, is designed for ischial weight bearing on the posterior brim. Quadrilateral sockets are still used for long-term wearers who have become accustomed to its weight-bearing and control characteristics but also remain an option for the individual with a transfemoral amputation with a long residual limb and for individuals who require UE aids for trunk stability (61) (Fig. 74-10). However, for the majority of individuals with new transfemoral amputations, the ICS is believed to provide a more normal anatomic alignment of the femur inside the prosthesis. This is accomplished by extending the socket trimlines proximally and contouring the medial aspect of the socket to capture the ischial tuberosity inside the socket rather than allowing the tuberosity to sit on the

**FIGURE 74-10.** Note the shapes between the quadrilateral (Quad) socket and the ICS. Also note the ischium sites inside the ICS socket rather than the socket brim (as does the quad socket).

posterior brim as in the quadrilateral socket. The ICS allows more effective hip and pelvic stabilizing forces to be developed during stance phase (61–63) which improves the medial-lateral control of the trunk. While the ICS is useful for all individuals with transfemoral amputations, the improved stability is especially beneficial for those with a short residual limb.

Several variants of the ICS have been introduced that include the normal shape-normal alignment, contoured adducted trochanter-controlled alignment method, the Sabolich ICS, and the Northwestern ICS and the M.A.S. (Marlo Anatomical Socket) ICS (61–65). These options vary somewhat in contour details but all retain the basic functional characteristics of ICS. No clear consensus has emerged favoring one-design variant over the others but all require considerable skill to fabricate correctly. Both the ICS and quadrilateral sockets can be fabricated as a rigid socket or by using a flexible thermoplastic inner socket supported by graphite-reinforced, laminated open framework (66,67). The advantages of the rigid frame-flexible liner type of socket designs are flexible walls that increase comfort, especially at the proximal brim, improved proprioception, accommodation of minor volume changes, less heat build-up, and enhanced suspension as the inner socket warms during use increasing its flexibility and improving the intimacy of the fit (63).

A number of interface liner systems and suspension options exist for the transfemoral prosthesis (Fig. 74-11)

**FIGURE 74-11.** Possible suspensions that could be used for the transfemoral amputee.

(56). The simplest liner system uses a hard socket with wool or cotton socks adjusted in plies to achieve a comfortable fit. Suspension for this type of prosthesis most commonly uses a Silesian belt or total elastic suspension (TES) belt. The Silesian belt attaches to the anterior and lateral portions of the proximal prosthetic socket and passes over the opposite iliac crest. The TES belt is made of the same neoprene material used for transtibial suspension sleeves. It slips over the outside of the prosthetic socket and surrounds the waist above the iliac crests to provide suspension. Both Silesian and TES suspension systems are simple to don, can be adapted for use by individuals with impaired hand function, and usually provide acceptable prosthetic limb suspension for low activity-level patients. Disadvantages include some inevitable pistoning of the prosthesis, reduced comfort due to bandage pressure, and heat or occasional dermatitis, especially with the TES belt. The TES and Silesian suspension systems can be used as a primary suspension system or coupled with other suspension options (discussed below) as an axillary suspension system when additional suspension security or rotation control is needed. Other suspension belt options include the pelvic band and hip joint. This option uses a single-axis hip joint integrated into the lateral socket wall, which is attached to a pelvic band and belt closely contoured about the iliac crest. The side joint and band discourage rotation of the prosthesis and extend the lateral lever arm stabilizing the prosthesis, making it especially useful for the short residual transfemoral prosthesis.

Suction socket suspension is the second major type of suspension for the individual with a transfemoral amputation and, whenever feasible, is generally the preferred option (56). Suction sockets are total contact sockets worn directly against the skin of the residual limb that incorporate a one-way air valve in the distal socket. To don the prosthesis, the individual with an amputation has to pull the residual limb into the socket. This can be accomplished using an elastic stockinette, an Ace bandage, or an “EZ pull” sock made from a thin slippery nylon fabric. An alternative method to pull socks uses a “wet fit” process in which a liquid powder is applied to the residual limb, temporarily lubricating the skin, which can then be slipped into the socket. Once the socket is donned, the suction valve is

functional and the remaining air is expelled through the valve, creating a small vacuum that holds the socket on the limb. For most users, suction suspension provides a very secure and comfortable suspension effect free from external belts or straps. Suction suspension requires a stable residual limb volume, and as a result is not a good option for preparatory prostheses when rapid limb shrinkage is expected. The presence of scar tissue can compromise the ability to maintain suction and may be poorly tolerated by the inherent high skin friction present in the socket. Prostheses that use suction sockets must be donned while standing and require both good balance and adequate hand strength and coordination to manipulate the pull sock and to install the valve. Difficulty with consistently pulling all of the proximal soft tissues of the thigh into the socket can lead to an adductor roll (a compression of the soft tissues of the medial groin between the proximal socket and the pelvis) that is painful and can lead to skin breakdown. Correcting this problem may require socket modifications, changes to the donning technique, or the use of external vacuum pumps to help elongate the tissue of the residual limb to promote a better fit (68).

A variant of the hard socket uses hypobaric socks, conventional limb socks with an impregnated silicone band near the proximal end of the sock. The silicone band provides a seal to prevent air leak, allowing for a partial suction suspension effect that, when coupled with an auxiliary Silesian suspension or TES, is an alternative option to the standard suction socket that can accommodate changing residual limb volume secondary to limb shrinkage or weight change.

Similar to a transtibial prosthesis, silicone and elastomeric gel suspension liners with a lanyard strap or pin attachment can be used to provide a beltless pseudosuction type of suspension. This suspension system provides good suspension, minimal pistoning, effective control of adductor rolls, and good comfort across a wide range of activity levels. Socks can be added over the suspension liner to accommodate for volume change of the residual limb. Effective use of gel liners can be problematic in the residual limb with excess or loose soft tissue because of difficulties in consistently donning the liner, excessive traction on soft tissue during swing, and poor rotational

**FIGURE 74-12.** Some of the computerized knees available. **Left to right** is the C-leg, Compact knee, Rheo knee, Smart Adaptive knee and the Plie knee. (Courtesy of Otto Bock, Ossur, Endolite and Freedom Innovations. See prosthetic manufacture Web site listing.)

control of the prosthesis. The use of auxiliary TES or Silesian suspension may be needed in this situation.

During the last decade, a wide variety of prosthetic knee joints have been designed, fabricated, and made commercially available. A recent survey cataloged over 200 knee units, ranging from the simple single-axis knee joints to the completely computerized knee units (Fig. 74-12). The primary purposes of the prosthetic knee are to provide stability during stance (to prevent knee buckling), either through alignment or mechanical means, knee motion during swing to permit clearance of the toe, and adequate flexion to allow the knee to bend when sitting. The knee unit should control the heel rise of the shank, assisting or resisting the acceleration and deceleration of the shank during the swing phase. The selection of an appropriate knee unit is primarily based on matching the stance phase stability features and the swing control aspects of the knee to the anticipated activity level and usage of the prosthesis (69–71). Hydraulic or pneumatic knee units are used for the K3 and K4 individual with an amputation and provide either swing phase control or swing and stance phase control for individuals who change their cadence frequently. For the K1 or K2 individual with an amputation who has difficulty maintaining knee stability during stance, locking knees and weight-activated-stance control knees are available. The four-bar, five-bar, and six-bar knee units are becoming increasingly popular due to the moveable centroid, which gives better stability of the knee. Table 74-5 outlines the major types of knee joints and their advantages and disadvantages.

The same pylon components (vertical shock pylons [VSPs] and rotators) that are available for the individual with an amputation at the transtibial level are also available at the transfemoral level. In addition, a thigh rotator can be added for the individual with a transfemoral amputation who has a need to cross the prosthetic leg for ADLs (i.e., riding in a car, donning and doffing clothing or shoes, etc.) (Fig. 74-13).

### Hip Disarticulation/Hemipelvectomy

Individuals with a transfemoral amputation, with less than 5 cm of residual femur, usually are fitted at hip disarticulation level. The standard prosthesis for a hip disarticulation is

**FIGURE 74-13.** Rotator adaptor for rotation to allow better access for donning and doffing clothing or comfort while in a vehicle. (Courtesy of Otto Bock, see Web site listing.)

the Canadian hip disarticulation prosthesis (Fig. 74-14). The socket of this prosthesis encloses the hemipelvis on the side of the amputation and extends around the hemipelvis of the non-amputated side, leaving an opening for the nonamputated LE. There is a flexible anterior wall with an opening that allows the prosthesis to be donned. Weight is borne on the ischial tuberosity of the amputated side. Endoskeletal prosthetic components are preferred for this level of amputation to reduce the overall weight. The endoskeletal hip joint has an extension assist, as does the knee unit, which usually is a constant-friction knee. Endoskeletal components may be made from aluminum, titanium, or carbon graphite composite materials. Traditionally, a single-axis or SACH foot with a soft heel has been the most common choice for the prosthetic foot. The newer lightweight foot/ankle combination such as the Endolite foot/ankle complex or the Endolite ankle with a Seattle Lite foot may be a better option for this level. A cosmetic cover completes the prosthetic prescription. If necessary, locking hip or knee joints can be used.

The prosthesis for a hemipelvectomy resembles that for the hip disarticulation except in the interior configuration of the socket. In the hemipelvectomy, most of the weight is borne by the soft tissues on the amputated side, with some of the weight being borne by the sacrum, the rib cage, and the opposite ischial tuberosity.

### Hemicorporectomy

Although rare, the hemicorporectomy (HCP), or translumbar amputation, has the most significant physiologic and psychologic implications. During this procedure the bony pelvis, pelvic contents, lower extremities, and external genitalia are removed following disarticulation of the lumbar spine and transection of the spinal cord. HCP is usually a last resort for patients with life-threatening conditions such as advanced pelvic tumors, pelvic osteomyelitis, crushing pelvic trauma, or intractable decubiti in

**TABLE 74.5** General Information on Prosthetic Knees and Usage

Type of Knee	Advantage	Disadvantage	Possible Usage
Single-axis constant friction	Simple Durable Low-maintenance	Only constant swing phase control No stance control Single cadence	Excellent for pediatrics Having good voluntary control of swing and stance phase but single cadence
Polycentric (not fluid control)	Varying stability through stance. Shortens shank during swing for better toe clearance. While sitting, some give natural and better cosmetic appearance.	Increased weight and bulk Complex mechanism Single cadence	Knee disartics Long transfemoral for appearance and short transfemoral for knee stability Weak hip extensors
Weight-activated—stance control	Do not have adequate control to manage a bending knee or good enough hip control to stabilize braking mechanism if weight applied with knee flexed 0–20 degrees Helpful for slower clients	Requires regular maintenance. Not very responsive for active walker. Gait modified to unload knee Single cadence	Geriatrics Short residual limb General debility Uneven surfaces
Manual lock	Total stability in stance phase.	No swing phase flexion, resulting in stiff knee gait Awkward in sitting	Patient requires mechanical stability in stance Last resort
<b>Fluid Control</b>			
Single-axis pneumatic control	Responds to changing gait speeds.	Higher cost May need more maintenance Heavier	From pediatrics to adults, with go control
Single-axis hydraulic control	Swing respond to changing gait speeds. If stance phase has hydraulic resistance to knee flexion during weight bearing	Higher cost May need more maintenance Heavier	From pediatrics to adults, with go control Excellent reliability. For the more active amputee
Polycentric and multiaxis fluid control	Varying stability through stance. Shortens shank during swing for better toe clearance. While sitting some give natural and better cosmetic appearance. Variable cadence	Higher cost May need more maintenance Heavier	Knee disartics Long transfemoral for appearance and short transfemoral for knee stability Range from homebound to highly active amputee
<b>Microprocessor Control</b>			
Single axis or multiaxis fluid control	On board computer adjusting knee for variable gait cycles. Energy saving	Highest cost Heavy Unproven track record for dependability	For the more active patients. Some computerized knees use a computer-regulated valve to adjust the swing phase resistance of a pneumatic cylinder. Some use the computer to control swing phase function and stance phase stability. Some systems using multiple sensors to send messages about changes walking back to the microchip 50 times a second.

**FIGURE 74-14.** Canadian type hip disarticulation with free motion hip joint and four bar knee with outline of cover. (Courtesy of Otto Bock, see Web site listing.)

the pelvic region. Once the amputation site is adequately healed then a prosthetist should begin fabrication of the prosthesis.

The prosthesis is bucket-shaped with two cut apertures to accommodate the patient's colostomy and ileostomy sites. This type of prosthesis is similar to those used in other cases of HCP (72). When using the prosthesis for the first time, the patient must limit the use and allow frequent checks for skin breakdown for the next several weeks. At first, the base of the prosthesis is attached to a flat board to provide a level seating surface and possibly later replaced with a rocker type board for greater mobility when transferring to and from a wheelchair and promoting easier wheelchair use.

## UE AMPUTATION

### General Principles of UE Amputation Management

The general approach to the care of the individual with a UE amputation parallels that used in treating a lower limb amputation outlined earlier in this chapter. The main differences will be highlighted and areas of unique management discussed.

### Preprosthetic Patient Evaluation and Management

The preprosthetic evaluation, whether performed preoperatively or postoperatively, should focus on identifying factors that will affect rehabilitation and prosthetic fitting. Of particular importance is the presence of coexisting musculoskeletal or neurologic compromise such as significant shoulder range of motion loss or brachial plexus injury that would compromise or prevent the successful use of prosthesis. Initial education about the rehabilitation process, prosthetic options, and a discussion of realistic expectations should occur during this stage.

### Postoperative Care

The options for postoperative care of the residual limb are similar to those used in the LE. Soft dressings along with stump shrinkers or elastic compressive stockinettes are the most commonly used wound care approach. In centers with experience in the application of RRDs, their use in the immediate and early postoperative period is advocated because of presumed benefits of better residual limb protection, edema control, and pain reduction. RRDs work best at the transradial amputation level because of the ease in suspending the cast. An additional advantage of RRDs is the ability to implement immediate or early postprosthetic fitting by attaching a hook, harness, and control system to the cast. Early prosthetic fitting is particularly important for the individual with a bilateral UE amputation to avoid the potentially profound psychology consequences resulting from the complete dependence that accompanies the loss of both UEs.

### Prosthetic Fitting

Even more so than in the individual with an LE amputation, an understanding of the individual's vocational and avocational needs, motivation in pursuing prosthetic fitting, availability of a supportive social network, and cosmetic concerns are critical in goal setting and decision making regarding prosthetic prescription. There are no fixed guidelines for deciding which individual with an upper limb amputation will benefit from a prosthetic limb. Factors that often prevent successful fitting and training include significant cognitive deficits, upper motor neuron syndromes that impair volitional coordination of the residual limb, plexopathies or peripheral nerve injuries, significant sensory loss, hyperpathia of the residual limb, or range of motion loss in the shoulder. The typical sequence of prosthetic rehabilitation involves initial fitting and training with a body-powered preparatory prostheses followed by a definite prosthesis when residual limb maturation has occurred 3 to 6 months postsurgery. Advantages of using a body-powered preparatory prosthesis include the greater ease of fitting, greater adaptability to changes in residual limb volume, early training in ADLs, and a lower cost compared to external powered devices. Since it is difficult to predict either the likelihood of long-term acceptance of an upper limb prosthesis or an individual's preferred type of prosthetic system (body or external powered), the preparatory prosthetic phase should be used to explore various prosthetic options. Different types of terminal devices

should be tried and the individual with a UE amputation given enough time to explore the advantages and disadvantages of using the prosthesis in a variety of home, work, and social settings. This type of clinical trial allows more informed decision making and participation of the patient at the time of definitive prosthetic prescription.

The overall acceptance and continued use of a prosthetic limb is influenced by a number of factors (73–76). Similar to the LE, as the amputation level moves more proximal, the prosthetic rejection rate increases. The majority of individuals with an amputation at the shoulder disarticulation or fore-quarter level ultimately reject prostheses. Approximately 40% of individuals with a THA become long-term users of a prosthetic limb. At the transradial amputation level, approximately 90% of individuals continue to use a prosthesis occasionally. More distal amputations in the hand have a lower rate of prosthetic limb acceptance, typically because of the greater preserved function of the residual limb. Individuals with bilateral amputations at all levels tend to have a higher acceptance rate for prosthetic limb use. Early work by Malone et al. (73) indicated that early fitting within 30 days postoperatively was associated with higher long-term acceptance. More recent studies (74,75) have not shown as strong a correlation, suggesting that even delayed fitting can be successful. Common reasons for rejecting a prosthetic limb include limited usefulness, excessive weight, residual limb pain, and poor durability (myoelectric prosthesis).

### Final Prosthetic Evaluation and Control Training

Prosthetic training is an important component of the rehabilitation process and affects the successful use and acceptance of the prosthesis (77). General strengthening and range of motion exercises for the proximal residual limb started in the preprosthetic phase should continue. After the prosthesis has been fabricated, it should be checked by the members of the prosthetic team to ensure that the fit is comfortable and that the control system is properly adjusted for maximum functional operation. During initial use and training, the prosthesis should be removed every 15 to 30 minutes to check for signs of excessive pressure or irritation that may occur with poor socket fit or overuse. As the skin tolerance increases, wearing time is gradually increased during the first few days of wear and thereafter more quickly. With a well-fitting prosthesis, an individual with a UE amputation can wear the limb for an entire day within a week or two of receiving it.

Specific training involves instruction in how to put on and remove the prosthesis, adjusting the number of sock plies, and how to clean and care for the residual limb and prosthesis. Initial skills are acquired to control the terminal device and to activate position and lock the elbow in the individual with a THA. Grasping and releasing objects, transferring objects, and positioning of the terminal device for functional activities should be practiced under the guidance and feedback of an experienced therapist. ADLs, homemaking, and occupational and recreational activities should be undertaken and simulated

in the training sessions. Successful prosthetic users rely on basic skills learned in therapy, which are supplemented and polished by practice at home during everyday tasks. The individual who is a long-term user of the upper limb often has very specific use patterns and preferences for components, harness type, and control cable adjustments. It is prudent to incorporate the desires of the individual into the decision-making and prescription process.

Control training for externally powered prostheses is more complex than for body-powered UE prostheses. The same goals as outlined for conventional prostheses are appropriate for myoelectric controlled prostheses. In addition, the individual must learn to separate, modulate, and sustain voluntary muscle contractions in the muscles selected to control the powered functions of the prosthesis. Training with an externally powered (electric) prosthesis often requires more time than with a body-powered prosthesis because more exacting individual muscle motions and quantity of muscle contraction are required for control of the prosthesis.

Adults and older children can be expected to practice specific tasks and routines, both in therapy and at home, as outlined by the therapist to achieve the necessary skills for independent function. The training time in a young child with a UE prosthesis will be significantly longer than that for an adult or older child.

### UE Prosthetic Follow-Up

The routine follow-up visits for an individual with a new amputation should occur initially 4 to 6 weeks after delivery of the prosthesis, then every 2 to 6 months until a definite prosthesis is prescribed. Once clinically stable in a definitive prosthesis, yearly clinic visits or whenever a problem arises, are usually adequate. At these follow-up visits, the individual's use and function with the prosthesis should be reviewed, difficulties or problems resolved, the fit and condition of the prosthesis evaluated, and the condition of the residual limb noted. If necessary, additional therapy may be suggested, repairs to the prosthesis made, medical problems with the residual limb addressed, and a new prosthesis prescribed if indicated. With average use, a UE prosthesis can be expected to be worn for 3 to 5 years before total replacement is necessary. The socket itself may need to be replaced more frequently than the other components.

Although our emphasis has been on prosthetic restoration, the focus of rehabilitation should remain on the individual with the UE amputation and his or her desired lifestyle following limb loss. Many individuals with a UE amputation do well without the aid of a prosthesis, and should not be viewed as having failed if they choose not to wear a prosthesis.

### Bilateral UE Amputations

The individual with a bilateral UE amputation is immediately faced with the loss of ability to perform almost every ADL. Early restoration of any ADL is important. Providing a utensil cuff, which can be attached to a residual arm, can assist the patient with feeding and tooth brushing. In the individual with a bilateral

**TABLE 74.6** General Information on Various Upper Limb Prostheses

Type	Advantages	Disadvantages
Cosmetic	Lighter Best cosmesis	High cost if custom made Least function
Body powered	Less harnessing Moderate cost Moderately lightweight Most durable Highest sensory feedback Variety of prehensors available for various activities	Low-cost glove stains easily Most body movement to operate Most harnessing Least satisfactory appearance
Battery powered (myoelectric and/or switch controlled)	Moderate or no harnessing Least body movement to operate Moderate cosmesis More function-proximal areas Stronger grasp in some cases	Increased energy expenditure Heaviest Most expensive Most maintenance Limited sensory feedback Extended therapy time
Hybrid (cable to elbow or TD and battery powered)	All-cable excursion to either elbow or TD	
If excursion to elbow and battery-powered TD	All-cable excursion to elbow Increased TD pinch	Battery-powered TD weights forearm (hard to lift but good for elbow disarticulation or long THA)
If excursion to TD and battery powered elbow	All-cable excursion to TD Low effort to position TD Low maintenance TD	Lower pinch for TD and least cosmetic

TD, terminal device; THA, transhumeral amputation.

UE amputation, early prosthetic fitting should be accomplished, even with temporary or preparatory prostheses. In the individual with a bilateral amputation, the longer residual limb usually assumes dominance. Special component considerations apply in this case. Wrist flexion units, at least on the dominant side or perhaps bilaterally, will permit mid-line activities such as shirt buttoning, belt buckling, and toileting. Also wrist rotator units, which provide terminal device positioning, provide for easier bilateral prosthetic use. Special toileting techniques must be taught for patient independence. In addition, foot skills should be reviewed, and LE mobilizing exercises should be performed.

### UE Prostheses

A UE prosthesis attempts to replace very complex functions. The hand is able to perform a wide range of functional activities ranging from fine dexterity tasks requiring light prehensile forces to gross grasping movements with great prehensile forces, all under the guidance of sensory feedback. To accomplish these tasks in the dynamic world around us, the coordinated movements of the proximal muscles and joints of the UE must position the hand for functional activities. The prosthetic replacement for the UE is a limited substitute for the lost body part. With practice, it can replace several of the simple grasping and manipulating functions of the hand through a mildly to moderately restricted sphere of functional reach. A critical limitation of all UE prosthetic limbs is the severe restriction in sensory feedback from the terminal device relegating its use to that of simply assisting bimanual activities.

The limited ability of the prosthetic limb to replace normal hand function typically results in a shift in hand dominance with amputation of the dominant hand.

UE prostheses can be divided into three groups: conventional or body-powered, external powered or electric, and passive or cosmetic. The advantages and disadvantages for each of the three general types of upper limb prostheses are presented in Table 74-6.

### Body-Powered Prostheses

Since the majority of individuals with UE amputation first learn to use a body-powered limb, an initial discussion of the function of various components (78,79) used in this type of prosthetic limb follows. Understanding the role, use, and limitations of body-powered prosthetic limbs forms the framework for subsequent discussions of externally powered devices. All conventional body-powered UE prostheses have these component parts:

- Socket
- Suspension
- Control cable system
- Terminal device
- Interposing joints (wrist, elbow, shoulder) as needed by the level of amputation

#### Socket

Traditionally UE prostheses have used a dual-wall socket design fabricated from lightweight plastic or graphite composite

**TABLE 74.7** General Information on UE Prosthetic Suspension Options

Suspension		Indications	Advantages	Disadvantages
Harness	Figure-8	Transradial Transhumeral Light to normal duty activities	Simple, durable, adjustable.	Axillary pressure reduces discomfort.
	Shoulder saddle and chest strap	Transhumeral Heavy lifting	Greater lifting ability, more comfortable than figure-8	Difficult to adjust in women because straps cross breasts. Reduced control compared to figure-8 harness
Self-suspending	Muenster Northwestern supracondylar	Wrist disarticulation Elbow disarticulation Short transradial Myoelectric transradial	Ease of use	Limited lifting capacity compared to harness systems, compromised cosmesis, reduced elbow flexion
Suction	Suction socket with air valve	Transhumeral with good soft-tissue cover	Secure suspension, elimination of suspension straps	Requires stable residual volume, harder to don than other suspension systems
	Gel sleeve with locking pin	Transradial Transhumeral Compromised limbs with scarring or impaired skin integrity.	Accommodate limb volume change with socks. Reduced skin shear.	Greater cleaning and hygiene requirements. Can be uncomfortable in hot climates

materials. In dual wall designs, a rigid inner socket is fabricated from a custom mold of the residual limb and is the primary interface between the user and the prosthesis. Comfort and function are directly tied to the quality of the fit of the inner socket. The outer socket wall is fabricated to have the general shape, length, and contour of the normal arm or forearm, and serves a cosmetic function and also supplies the foundation for the mounting of required components. This type of socket is durable and easily accommodates variation in residual limb volume using socks to adjust the fit.

An alternative approach to the design of the socket parallels the rigid frame, flexible liner approach used in lower limb prostheses. An inner socket is fabricated from flexible plastic materials to provide a total contact fit and is optimized for the use of suction suspension. Surrounding the inner socket is a rigid frame that provides the structural integrity of the socket. Windows in the outer socket allow for the movement of the muscles of residual limb to enhance comfort.

### Suspension

The suspension system must hold the prosthesis securely to the residual limb and accommodate and distribute the forces associated with the weight of the prosthesis and any superimposed lifting loads. Suspension systems can be classified as harness-based, self-suspending sockets, or suction. Table 74-7 outlines the types of harnesses and their suggested uses, advantages, and disadvantages.

The most commonly used suspension for body-powered prostheses are variants of the harness-based system. The most commonly used harness is the figure-8 strap (Fig. 74-15). On

the intact side, the harness loops around the axilla anchoring the limb and providing the counterforce for suspension and control cable forces. On the prosthetic side, the anterior strap carries the major suspending forces to the prosthesis by attaching directly to the socket (transhumeral) or indirectly through an intermediate Y-strap and triceps pad (transradial). The posterior strap on the prosthetic side attaches to the control cable. For heavier lifting activities or when axillary pressure from a figure-8 harness is unacceptable, a shoulder saddle with chest strap system is a useful alternative suspension system. A leather or flexible plastic saddle is positioned over the prosthetic side shoulder and is secured using a chest strap that wraps around the intact chest wall in an infra-axillary location. The suspension of the prosthesis occurs through an inverted U-shaped cable or strap that is anchored to the top of the saddle and drapes downward to attach to the front and back of the prosthetic socket (transhumeral) or triceps pad (transradial). The control cable attaches to the posterior aspect of the chest strap.

Self-suspending socket designs are used when the bony configuration of the residual limb allows suspension, similar to the effect used in Syme amputations. Self-suspending sockets are largely limited to wrist and elbow disarticulations. In both harness and self-suspending systems, socks can be worn to optimize fit and improve comfort.

Suction suspension sockets are similar to those available to the individual with an LE amputation and use either a total contact socket with a one-way air valve or a roll-on silicone gel sleeve with a locking pin. Suction sockets are appropriate primarily for the transhumeral residual limb with good soft-tissue

**FIGURE 74-15.** The transradial amputee has two types of harnessing. **Top:** The figure 8 harness and the next shows the shoulder saddle and chest strap harness. The terminal device is activated by arm flexion or by bicipital abduction. **Bottom:** For the transhumeral amputee, the same motion stated above will move the elbow and operate the terminal device once the elbow is in the locked position. To lock or unlock the elbow the amputee must simultaneously use arm extension, shoulder depression, and arm abduction. Figure 8 and shoulder saddle for the transradial and transhumeral body powered harness. Shoulder saddle harnessing is used for the heavier lifting activities or axillary pressure cannot be tolerated.

envelope, an absence of invaginated scarring, and a stable volume. Donning the suction socket with air valve involves the use of water-based lubricants or a pull sock to seat the residual limb into the socket. The one-way air valve creates suction inside of the socket, maintaining suspension. When using a silicone gel (or similar polymer materials) sleeve with a distal attachment pin, the sleeve is rolled onto the residual limb and inserted into the socket where the pin mates with a locking mechanism. Suspension is accomplished through a combination of suction and skin friction.

### Control Cable Mechanism

Body-powered prosthetic limbs use cables to link movements of the shoulder and humerus to activation of the terminal device and elbow. The movements that are captured for control include scapular abduction, shoulder depression and abduction, and humeral flexion. Control cables used to activate a single prosthetic component such as the terminal device are known as single-control cables or Bowden cables. Dual-control cable systems use the same cable to control two prosthetic functions, typically elbow flexion and terminal device opening in the transhumeral prosthesis. The control cable is attached to the figure-8 or chest strap harness used for suspension of the prosthesis. When a body-powered prosthesis incorporates a self-suspending socket design or suction suspension, a simple figure-8 harness strap system is required to allow control functions to be performed.

### Terminal Device

Terminal devices for body-powered prostheses can be hooks, functional or active hands, cosmetic or passive hands, or special terminal devices designed for specific activities (e.g., bowling ball terminal device, golf club holder). Hook-style terminal devices provide the equivalent of a lateral pinch grip while active hand terminal devices provide a three-point chuck action (80). The most commonly used active terminal device is the voluntary-opening hook. While different voluntary-opening hook designs are available for various applications, the most commonly prescribed design for general use is the Dorrance 5X, 5XA, and 7 (Hosmer Dorrance, Campbell, CA) (Fig. 74-16). With voluntary-opening devices, the individual with a UE amputation provides power through a cabling system to open the terminal device and relies on springs or rubber bands to provide the closing prehensile force. Typical closing forces range from 5 to 10 lb. Voluntary-opening active hands are available and in general are more cosmetic, but are heavier, interfere with visualizing the object being grasped, and provide lower prehensile forces. Voluntary-closing terminal devices allow the individual to provide a variable prehensile force transmitted through the control cable to the terminal device. Voluntary closing devices are capable of providing larger prehensile forces up to 20 to 25 lb (9 to 11 kg) and provide indirect sensory feedback through the force exerted on the control cable. A significant disadvantage of voluntary-closing devices is the need for a constant pull on the control cable during prolonged grasping, a skill that is difficult to accomplish during dynamic tasks. Passive (cosmetic) hands are lighter than active

**FIGURE 74-16.** Most common terminal devices. (Courtesy of Hosmer-Dorrance, see Web site listing.)

hands and can be passively positioned but provide little if any function. A cosmetic glove tinted to approximate the individual's skin color covers both of these hands.

### Wrist Unit

Wrist units provide a receptacle for connecting the terminal device to the prosthesis and permit prepositioning of the terminal device for functional activities (i.e., rotation for all units and flexion if the appropriate unit is used). Wrist rotation is performed using the intact hand or by pushing the terminal device against a firm surface and is held in place with either friction or a mechanical lock. Friction control wrist units are easily positioned but can slip when lifting heavier loads. A locking wrist unit enhances the use of the terminal device with heavier objects or where leverage with the terminal device is important for function. A wrist flexion unit allows the terminal device to be positioned in flexion, enhancing the ability to perform activities close to the body, a feature that is

**FIGURE 74-17.** Thumb prosthesis set in position to allow for grasping and object manipulation.

important for the individual with a bilateral UE amputation. A quick-disconnect option permits the easy interchange of different terminal devices, such as a hook for a hand.

Additional details regarding components, sockets, suspension, and control systems are discussed where appropriate in the following sections relating to specific levels of amputation.

## Prostheses by Level of Amputation

### Partial Hand

For partial hand amputations (e.g., phalanges, ray resections, transmetacarpal), a prosthesis may not be necessary. To be functionally useful, the residual hand needs to be able to provide a rudimentary grasp. This requires two opposing posts that can be moved into contact with each other to provide a prehensile force. When possible, surgical reconstruction of the remaining hand is often the preferred approach to preserving or enhancing function while maintaining sensation. When only one movable digit remains, as in a transmetacarpal amputation of digits 2 through 5, either an open or mitt-shaped prosthetic opposition post can be used to provide a stable surface for opposition with the thumb. In general, the substantial variability in the anatomy of the remaining partial hand requires creative custom solutions to optimize function (Fig. 74-17). At times, an individual with a UE amputation may require devices customized for specific activities. A cosmetic prosthesis is frequently provided for this level of amputation. Long-term usage varies but the majority of individuals continue to wear them at least occasionally for social situations (80).

### Transradial Amputation/Wrist Disarticulation

The length of the bony forearm, measured from the medial epicondyle, classifies transradial amputations as: very short (<35%), short (35% to 55%), and long (55% to 90%). Longer residual limb length enhances the forearm lever, making lifting easier, and allows capturing residual pronation-supination motion of the forearm. Long transradial residual limbs retain from 60 to 120 degrees of supination-pronation, which decreases to less than 60 degrees in short transradial residual limbs. For short and long transradial amputations, a dual-wall socket is attached to a triceps pad with flexible elbow hinges (straps) to allow pronation-supination. The triceps pad helps to distribute suspension forces and is needed to anchor the control cable. Most commonly, a figure-8 harness system is used for suspension and control. For very short transradial amputation levels, rigid hinges are generally used to provide greater stability of the socket on the residual limb. With transradial amputations, in which range of motion is limited at the elbow, polycentric elbow joints or a split socket with step-up hinges

can be used to provide additional flexion. The additional flexion gained with the use of these elbow hinges is offset by a loss of elbow flexion power and lifting ability.

The wrist disarticulation (WD) prosthesis is a variant of the transradial prosthesis. Because WD spares the distal radial-ulnar joint, full forearm supination-pronation is preserved. Socket designs for the WD level are flattened distally to form an oval to capture supination-pronation, allowing active rotational positioning of the terminal device during activities. The distal flare of the residual limb can be taken advantage of to fabricate a self-suspending socket but this usually leads to a bulbous, cosmetically compromised appearance similar to that occurring in the LE Syme amputation. The long residual limb necessitates the use of a special thin wrist unit to minimize the overall length of the prosthesis. If cosmesis is of primary importance to the patient, a long transradial amputation may be a more appropriate amputation level.

An example for the prescription of a transradial/WD limb could read: *dual-wall total contact socket, flexible elbow hinges, triceps pad, figure-8 harness, single control cable, constant friction wrist unit with quick disconnect, 5XA hook, and cosmetic hand.*

### Transhumeral Amputation/Elbow Disarticulation

The length of the residual humerus measured from the acromion classifies the transhumeral amputation (THA) as: humeral neck (<30%), short transhumeral (30% to 50%), standard transhumeral (50% to 90%), and elbow disarticulation (90% to 100%). For short and standard transhumeral residual limb lengths, the traditional dual-wall socket extends to just below the acromion and attaches to either a figure-8 or a shoulder saddle and chest strap harness for suspension. With shorter residual limbs, securing the socket to the residual, especially under load, is more difficult. To accommodate this problem, the socket extends proximal and medial to the acromion, creating a partial shoulder cap. This socket design often can be suspended with only a chest strap, but other harness systems can be used for additional security or to improve control functions. Suction socket suspension systems are becoming the preferred system for individuals with a THA because of the improved suspension and greater ability to position the limb for activities. Even when suction suspension systems are used, an axillary harness is needed for control and can augment suspension, especially when lifting larger loads. Suction suspension, when used with externally powered myoelectric components, can result in a self-suspending prosthesis free of any harness.

The standard elbow component for the transhumeral prosthesis is the internal elbow joint. Internal elbow units allow for 135 degrees of flexion and can be manually locked into a number of preset flexed positions. The standard internal elbow unit incorporates a turntable that allows passive internal or external rotation of the forearm. Elbow spring-lift assist units are available and are generally recommended for internal elbow units to help counterbalance the weight of the forearm, making elbow flexion easier for the individual with an amputation. This unit requires approximately 5 cm of length. If the level of amputation is less than 2 in (5 cm)

proximal to the epicondyles, then an internal elbow unit cannot be used unless an asymmetric elbow position compared to the intact limb is cosmetically acceptable. When the internal elbow unit cannot be used, locking external elbow joints are available but these are less durable and less cosmetic.

The control system for the transhumeral prosthesis uses two cables: a dual control cable that controls the elbow and terminal device and a secondary elbow locking cable. To control the prosthetic limb, the individual with an amputation uses scapular protraction and humeral flexion to flex the elbow into the desired position. The elbow is locked using the secondary control cable. Once locked, the same shoulder movements that powered the elbow are now available to activate the terminal device. Locking the elbow is typically accomplished by using a control cable that is routed along the anterior aspect of the socket and attaches to the front of the harness. Shoulder depression and humeral extension movements are used to lock-unlock the elbow.

An elbow disarticulation prosthesis is a variant of the transhumeral prosthesis. The socket is flat and broad distally to conform to the anatomic configuration of the epicondyles of the distal humerus. This design provides some self-suspension and allows the individual with an amputation active rotation of the prosthesis (internal and external rotation of the humerus). The length of the residual limb requires the use of external elbow joints, with a cable-operated locking mechanism. The harness is either a figure-8 or a shoulder saddle and chest strap. The control system for this level is the same as for the individual with a more proximal THA.

Example prescription for a short transhumeral prosthetic limb read as: *flexible wall/rigid frame suction socket, figure-8 axillary suspension and control harness, dual-control cable, internal locking elbow with turntable and flexion assist, lightweight forearm shell, constant friction wrist unit with quick disconnect, 5XA hook, and cosmetic hand.*

### Shoulder Disarticulation/Forequarter Amputation

For shoulder disarticulation and forequarter amputation, the socket extends onto the thorax to suspend and stabilize the prosthesis. The portion of the thorax covered by the socket is more extensive for the forequarter amputation. In some cases, an open-frame socket rather than a plastic laminated socket is chosen for these levels to reduce prosthetic weight and to minimize heat buildup by reducing the amount of skin coverage.

Prosthetic components are similar to those for the transhumeral prosthesis with the addition of a shoulder unit, which allows passive positioning of the shoulder joint in flexion-extension and abduction-adduction. Chest straps are attached to the anterior and posterior socket for suspension. The loss of ipsilateral shoulder motion for control purposes severely compromises the use of the prosthesis. A harness and control cable system that uses three individual cables can be used. Individual cables use intact side humeral flexion for prosthetic elbow control, chest expansion for terminal device control, and a manual nudge or pull cable for elbow locking.

The body-powered prosthesis is cumbersome to don, has limited functionality, and is often used mainly for cosmesis. The difficulty in providing suitable body-powered prostheses at these proximal amputation levels argues against their routine use. For many individuals, a cosmetic limb is sufficient. For the highly motivated individual, externally powered prostheses may be more functional and hence can be considered.

### Externally Powered Prostheses

Externally powered prosthetic limbs use small electric motors incorporated into the prosthetic component to control its function. Reliable external power units are available for terminal device operation, wrist rotation, and elbow flexion-extension. Myoelectric signals or switches control these electric motors. It is often difficult to predict the preferred type of power for the prosthetic limb for a particular individual until trial use of both has occurred. Compared to body-powered prostheses, external powered prostheses are typically heavier, more costly, and less durable, especially if manual labor activities are frequently performed. Important advantages of external-powered prostheses compared to body-powered devices include improved comfort due to the reduced harness needs, better control, and lifting capacity for short transhumeral and shoulder disarticulation amputation levels, and the greater terminal device grip force of electric hooks and hands. In the case of the transradial level amputation, the prosthesis can use a self-suspending socket that eliminates the need for a harness (Fig. 74-18).

The preferred control system for external-powered prostheses is myoelectrical control. Myoelectrical control uses surface electrodes embedded in the prosthetic socket that make contact with the skin and detect muscle action potentials from voluntarily contracting muscles in the residual limb. The myoelectric signal controls an electric motor to provide a function (e.g., terminal device operation, wrist rotation, elbow flexion). Prior to the prescription and fitting of a myoelectric prosthesis, the individual's ability to reliably contract and relax at least one muscle group in the residual limb should be ascertained. This can be accomplished using electromyographic biofeedback equipment or a myoelectric tester to identify the most appropriate electrode control location(s). Several different types of myoelectric controllers are available depending on the number of prosthetic functions that need to be controlled

and the number of useful electrode sites identified. The dual-electrode system uses two sets of electrodes positioned over antagonist muscles allowing natural and intuitive myoelectric control to occur. For example, at the transradial level, activation of the forearm flexor muscles closes the terminal device while activation of the forearm extensors opens the terminal device. Most contemporary myoelectric control systems use proportional control so that the speed or strength of terminal device activation varies with the intensity of muscle contraction. When there are an inadequate number of usable electrode sites available to control all desired functions of the prosthesis, alternative control strategies can be used. Single-site controllers use the strength of voluntary contraction from a single electrode (i.e., amplitude of the myoelectric signal) to control the motion (i.e., a weak contraction will close the terminal device and a strong contraction will open the terminal device) (81). Sequential or multistate controllers use the same electrode pair to control several functions (e.g., terminal device control and elbow activation). This type of controller uses a brief co-contraction to switch between control modes. Any of the alternative control schemes take longer to learn and are not consistently mastered by all individuals with an amputation.

When myoelectric control is not available or there are not enough electrode sites available, switches incorporated into the prosthetic socket or the harness can be used to implement or augment the control of various components. Simple on-off switches can be used to implement basic control of a powered component. More sophisticated servo control techniques based on position or force switches in the harness systems can be used to provide proportional control (82).

Myoelectric prosthetic components are available and sized to fit a wide range of people, from infants to adults. Most myoelectric terminal devices are hands, but some electric hook designs are also available. Myoelectrically controlled prostheses can and have been fit immediately after surgery (83), but it is generally recommended that fitting be delayed until the residual limb is healed and the limb volume has stabilized. A stable limb volume is needed to ensure a consistent socket fit and reproducible electrode position and skin contact. Myoelectric components have been combined with body-powered components to result in a hybrid prosthesis, which may provide better function for some individuals with an amputation than either myoelectric or body-powered control used alone.

**FIGURE 74-18.** Otto Bock self-suspending transradial myoprosthesis and the internal placement of the electronic components. (Courtesy of Otto Bock, see Web site listing.)

### Cosmetic Prosthesis

A conventional body-powered or myoelectric prosthesis with a hand terminal device supplies adequate cosmesis for many individuals with a UE amputation. Using custom covers that are color and texture matched to the skin of the intact side can enhance cosmesis. These covers are expensive and have a limited life expectancy if used during functional activities. When an individual with an amputation is not a candidate for an active prosthetic limb, a cosmetic prosthetic can be fabricated using lightweight components that can be passively positioned to create a symmetric body image while wearing clothing.

## SPECIAL ISSUES IN THE CARE OF INDIVIDUALS WITH AN AMPUTATION

### Pain

Pain is a common problem following amputation. Identifying the etiology of a pain complaint is often challenging because of the limited ability to examine the residual limb during prosthetic use and overlapping symptoms from different pain sources. The initial decision required in addressing pain complaints is to differentiate phantom limb pain from residual limb pain.

### Phantom Limb Sensation/Pain

Phantom sensation, defined as the awareness of a nonpainful sensation in the amputated part of the limb, occurs in nearly all acquired amputations (84–86). Phantom sensation is most prominent immediately after amputation and generally diminishes over time, often in a telescoping fashion. The most vivid sensations are typically in the distal portion of the limb. Generally phantom limb sensations that persist do not require treatment. An occasional problem with phantom sensation occurs when individuals are confused by the phantom sensation and attempt to walk without using a prosthesis.

Phantom pain is pain perceived in the amputated portion of the extremity. The incidence of phantom pain has been difficult to determine with reported frequency ranging from 4% to 80% (70,85,86). Like phantom sensation, phantom pain is most common immediately after amputation and usually becomes less frequent, less intense, and shorter in duration over time. Persistent phantom pain requiring treatment occurs in approximately 5% of individuals with an amputation. Phantom pain is often described as burning, cramping, stabbing, or squeezing but is sometimes reported as bizarre contortions of the limb. The pain may be generalized but more commonly it is experienced mainly in the distal parts of the missing limb. The cause and underlying physiology of phantom pain remain poorly understood but the incidence of phantom pain has been associated with the presence of preamputation pain, phantom sensation, and residual limb pain. The correlation between preamputation pain and the subsequent development of phantom pain has led to attempts at preventing phantom pain by controlling periampputation limb pain with continuous epidural or peripheral nerve anesthesia. These attempts have shown mixed effectiveness (86). Once established, the successful treatment of phantom pain can be difficult and many therapeutic modalities have been tried (70,87–90). Although convincing evidence-based algorithms for the treatment of phantom pain do not exist, empiric clinical guidelines are frequently used. Medication is usually the first line of treatment employing tricyclic antidepressants and anticonvulsants (e.g., carbamazepine, gabapentin), either alone or in combination. Other drugs that have been used with some success include mexiletine, calcitonin, *N*-methyl-D-aspartate (NMDA) receptor antagonists, and opioids. Evaluation and correction of any coexisting residual limb pain or prosthetic fit problems is also an important component of the initial management of phantom pain. Range-of-motion exercises, relaxation exercises,

residual limb massage, transcutaneous electrical nerve stimulation (TENS), compressive stocking, and encouraging prosthesis use have little risk and may be useful adjuncts to medical management. Since problematic phantom pain often occurs only intermittently and is typically short-lived, the patient's participation in decision making is essential to weigh possible benefits of drug trials with the inconvenience and possible side effects of medications that need to be taken on a regular, continuous basis. Surgical treatments have not been shown to provide lasting pain relief and are rarely used.

### Residual Limb Pain

In contrast to phantom limb pain, residual limb pain is the pain perceived as originating in and affecting the residual portion of the limb. Persistent residual limb pain occurs in up to 70% of individuals with lower limb amputation with about half reporting the pain as moderately to severely bothersome (85–88). Residual limb pain is commonly described as aching, sharp, throbbing, and burning in character. The underlying causes of residual limb pain can be classified as intrinsic or extrinsic.

*Intrinsic residual limb pain* is caused by changes or complications in the underlying neurovascular, bony, or soft tissues of the residual limb. Neuromas develop in all residual limbs after amputation but may only become problematic when entrapped in scar or positioned such that they are exposed to external mechanical loading. Diagnosing an underlying neuroma as the cause of pain can be difficult. When present, neuropathic symptoms including typical dysesthetic pain descriptors, radiation of pain in a specific nerve distribution, and the presence of pain when not using a prosthesis are helpful diagnostic aids but at times the pain location and description is nonspecific. Neuroma-related pain may be precipitated by tapping (Tinel's sign), direct compression from manual palpation or socket pressure, or traction on an adherent scarred nerve. Larger neuromas can be imaged with magnetic resonance imaging (91). When prosthetic use exacerbates neuroma pain, initial treatment interventions should include prosthetic modifications that attempt to reduce loading of pressure-sensitive areas. Useful approaches include the use of gel socks or liners to better distribute loads and to reduce shearing of adherent tissues, flexible sockets, or socket modification to relieve sensitive areas. Infiltration of the perineuromal region with local anesthetics combined with steroids can be a useful diagnostic and therapeutic procedure. If the injection relieves the pain, a series of similar injections over several months can be attempted to try to achieve lasting relief. When neuroma pain persists and limits function, surgery to resect and move the neuroma to a more protected location can often be helpful. However, following neuroma resection, the neuroma will reform and, on occasion, again become symptomatic.

Bony overgrowth from the distal end of the residual limb skeletal elements occasionally occurs in adults but is primarily a problem that occurs in children with an amputation. Heterotopic bone can form in the soft tissues of the residual limb and may follow trauma, hematoma, or fracture of the residual limb. Poorly contoured bone edges following surgery

can lead to regions of high-pressure concentration. In any of these situations, the abnormal bone leads to localized tissue compression, pain, and tenderness that can progress to the development of adventitial bursa or soft-tissue ulceration. Diagnosis is made with plain radiographs of the residual limb. Management is focused on prosthetic socket modifications to offload painful areas; but achieving a lasting comfortable fit can be difficult. When prosthetic approaches fail, surgical revision is typically needed.

Osteomyelitis, tumor recurrence, stress fractures, and persistent limb ischemia also may occur in patients after amputation. These may cause more generalized residual limb pain and require medical and surgical management.

*Extrinsic residual limb pain* is caused by a mismatch between residual limb tissue tolerance and prosthetic loads imposed on the soft tissues. Poor socket fit or limb malalignment are the main causes. The coexistence of a compromised residual limb from intrinsic pathology reduces the safety margin between tissue tolerance and prosthetic socket loads, making it more difficult to achieve and maintain a comfortable fit. The ability to attain a comfortable socket fit is one of the most important aspects of prosthetic acceptance and function. Most contemporary prosthetic sockets are designed for total contact with modifications to the socket shape to preferentially load weight-tolerance tissues. Socket fit is inevitably compromised with body weight changes or residual limb soft-tissue atrophy over time. Clinical manifestations of poor fit or excessive local tissue loading include a gradual onset of pain while using a previously comfortable prosthesis, erythema persisting more than 15 to 20 minutes after wearing the limb, or the development of blisters, bursas, calluses, or skin ulceration. Changing the number of sock plies, adding pads to the socket, relieving high-pressure areas, or substituting a gel liner for socks can often restore a comfortable fit and prolong the useful life of a socket. When minor modifications fail, a replacement socket will need to be fabricated.

Malalignment of lower limb prostheses can create abnormally high or prolonged loading forces in the residual limb leading to pain even when the socket fit is acceptable. In the individual with a transtibial amputation, sagittal plane alignment problems most commonly affect the distal tibia region while frontal plane malalignment primarily affects loading forces along the fibula. In the individual with a transfemoral amputation, distal femur pain is often seen with alignment problems.

### Choke Syndrome

A specific socket fit problem, almost exclusively seen in the individual with an LE amputation, is the choke syndrome. A choke syndrome develops when there is a simultaneous impairment of venous return from a prosthetic socket that is too tight proximally and a lack of total contact between the residual limb and the socket. Edema develops in the residual limb where total contact is lost. Most commonly, this occurs in the distal aspect of the transtibial residual limb as atrophy takes place over time and additional socks are used to fill in for the loss of soft-tissue volume. Because there is no corresponding volume change in the proximal bony aspect of the limb, the fit becomes too

tight and constricts the venous return. Initially, a circumscribed indurated region develops while wearing the prosthesis. If significant edema develops acutely, there can be associated weeping or blistering of the skin. The area of choke is tender to palpation and is prone to developing cellulitis. As the choke syndrome becomes chronic, the tissues become increasingly thickened and indurated, verrucous hyperplasia develops, and skin becomes hyperpigmented because of hemosiderin deposition. Choke syndromes are treated by relieving the proximal constriction and restoring total contact between the residual limb and the socket (90,92). When the choke syndrome is mild, reducing the number of socks to decrease proximal residual limb constriction and adding or modifying the distal end pad may be adequate but typically a new total contact socket is needed.

### Dermatologic Disorders

Dermatologic problems are common, particularly in the individual with an LE amputation, with surveys estimating that 30% to 50% of individuals with amputations experience one or more skin problems because of a prosthesis (91–94). Dermatologic complaints can be classified as related to hyperhidrosis, physical effects of prosthetic use, contact dermatitis, and infection.

Hyperhidrosis, while not indicative of underlying disease, is one of the most common skin-related complaints and has become more common with the introduction of silicone liners in the 1990s. An increase in sweating is reported by about half of the patients with the use of silicone liners. Over several weeks, adaptation typically occurs and excessive sweating often resolves. Persistent hyperhidrosis makes it more difficult to maintain hygiene, increases the likelihood of skin maceration, and may contribute to the development of contact dermatitis (92–95). When using suction sockets, suspension effectiveness can be compromised. Problematic sweating can be controlled by using concentrated antiperspirants, such as Drysol (Person & Covey, Glendale, CA), on the residual limb or by changing to a liner system that allows the individual with an amputation to wear socks directly against the skin.

The skin of the residual limb is subjected to repeated shear, frictional, and loading forces. The physical effects of these repetitive loads can lead to keratin plugging of sebaceous glands and follicular hyperkeratosis, leading to the development of epidermoid cysts, folliculitis, and dermal granulomas. Cysts are frequently very tender and can spontaneously break open or become secondarily infected. Commonly affected areas are those that are subjected to high loading and shearing forces such as the groin region in the individual with a transfemoral amputation and the medial tibial flare and popliteal fossa in the individual with a transtibial amputation. Treatment is directed at local skin care as well as prosthetic modifications to reduce mechanical skin forces. Meticulous hygiene needs to be encouraged to keep skin, socks, and liner clean. Cosmetic or acne scrub pads can be used to help keep skin pores open. Warm compresses to promote drainage and oral antibiotics are useful in managing folliculitis and infected cysts. Larger and more persistent sebaceous cysts may require surgical drainage

or excision. Concurrent with medical management, a review of prosthetic fit and alignment to ensure that loading of the affected region is optimized should be undertaken. Recurring problems can be helped with the use of prosthetic components that reduce residual limb shear and loading forces. These include gel liners, rotators, VSPs, and multiaxis ankle/foot devices.

Allergic or contact dermatitis accounts for approximately 20% of prosthetic-related dermatoses (93). Clinical symptoms range from mild lichenification or scaling to weeping eczema. A wide variety of offending agents has been identified. Detergents, scented emollients, creams, and talcs used for skin care should be considered as possible allergens and discontinued or changed. The use of gel sheaths and liners may result in contact dermatitis. The exact allergen is difficult to identify and is probably residual soap used in cleaning or chemical additives used in liner manufacturing rather than the hypoallergenic silicone material itself. If continued use of gel-type liners is needed, it is reasonable to switch to a different manufacturer or change to a different liner base material (e.g., silicone to urethane) to empirically attempt to resolve the rash. Neoprene, resins used in socket fabrication, and dyes and tanning agents used in leather are also potential allergens. If empiric trials of different materials cannot identify the allergen, patch testing for 24 to 48 hours with a small piece of the suspected material on the forearm may be helpful.

The use of gel sheaths, liners, and suspension sleeves can create a moist warm environment that may contribute to contact dermatitis, bacterial, and fungal skin infections. Attention to proper skin care and liner cleansing can minimize skin disorders. At times, wearing natural fiber socks or a nylon sheath between the liner and residual limb can absorb or wick away moisture and reduce skin problems.

### Pediatric Limb Deficiency or Amputation

When amputations are performed in children for disease, tumor, trauma, or congenital skeletal deficiency for prosthetic

fitting, a disarticulation-level amputation is preferred rather than an amputation through a long bone when the resulting level of function with a prosthesis will be similar. Approximately 12% of children with acquired amputations experience a condition known as bony overgrowth. Bony overgrowth is the appositional deposition of bone at the end of the amputated long bone. This bone growth results in a spike-like formation at the end of the bone that has a thin cortex and no medullary canal. The bone frequently grows faster than the overlying skin and soft tissues; a bursa may develop over the sharp end, or the bone actually may protrude through the skin with subsequent development of cellulitis and osteomyelitis. Overgrowth is seen (in decreasing frequency) most frequently in the humerus, fibula, tibia, and femur. It has been reported in the congenital limb deficiencies, but rarely. Several treatment approaches have been advocated for the management of this problem. Success is limited, but the technique proposed by Marquardt in which the distal end of the bone is capped with a cartilage epiphysis is the best of the surgical options available to manage this problem (15).

For the child with a congenital skeletal deficiency, the initial prosthesis for the UE usually is fitted when the child has attained independent sitting balance, or at approximately 6 months of age (96–99) (Table 74-8). For the LE, the initial prosthesis is fitted when the child begins to pull to a stand, which generally is between 9 and 14 months. Young children and infants usually learn to use their prostheses by incorporating them as part of play activities rather than through specific exercises. Prosthetic training periods for children may last only for several minutes at a time because of limited attention span, and they may require much longer periods of free play interspersed between actual training sessions. It is important that parents be instructed in techniques to help their children attain the necessary prosthetic skills because much of the training in the use of the prosthesis will occur in the home rather than in the clinic. It is also important to understand when working

**TABLE 74.8 Guidelines for Pediatric Prosthetic Fitting**

Amputation Level	Age for Prosthetic Fitting	Developmental Milestones	Prosthetic Prescription
Transradial	6–7 mo	Sitting balance, reaches across mid-line for bimanual object manipulation	Body-powered—passive mitt, self-suspending socket
	9–15 mo		Externally powered for greater grip strength, single control site (voluntary opening, auto close)
	24–36 mo		Change to two site control for voluntary opening and closing
Transhumeral	6–7 mo	Same as for transradial	Body-powered—passive mitt and elbow, activate elbow at 18 mo.
	24–48 mo		Externally powered terminal device, when terminal device control mastered, activate the elbow.
Transtibial	9–12 mo	Child pulls to stand	PTB, supracondylar strap
Transfemoral	9–12 mo	Child pulls to stand	ICS, belt suspension, no knee unit until ages 3–4.

**TABLE 74.9 Comparison of Children Versus Adults with an Amputation (15,99–101)**

General		
Dynamic (growing)	vs.	Adynamic (decelerates—aging)
Dependent	vs.	Independent
Untrained (life disciplines)	vs.	Trained
Irresponsible	vs.	Responsible
Malleable	vs.	Less malleable
Physical		
Growing	vs.	Static
Immature	vs.	Mature
Longitudinal growth	vs.	Nonlongitudinal growth
Circumferential growth	vs.	Circumferential growth (dietary)
Circulation and tissue tolerance are ideal	vs.	Circulation and tolerance vary with age and health
	Influences surgical indications, site of amputation and goals of training	
Social		
Member of family group	vs.	Independent person
Few independent social responsibilities	vs.	Variable responsibilities; depends on age, marriage, parenthood, etc.
Adjustment relatively easy	vs.	Adjustment less easy because of fixed social environment
Economic		
By family	vs.	By patient
Not self-supporting	vs.	Self-supporting or at least contributes to the economic welfare of the family
Amputation not of economic importance	vs.	Amputation may interfere with established economic status
Education		
Process of obtaining basic education	vs.	Usually completed
Advanced education can be planned to include handicap and its limitation and needs	vs.	Age often makes long reeducation and training difficult, if not impossible
Vocational		
Not selected or established	vs.	Established
Oriented around handicap	vs.	Must reorient vocationally because of handicap
Psychological		
Because of immaturity of development, may not have the profound changes sometimes seen in the adult. Usually reflects family (parental) reaction to the amputation or deformity. In general, is not a great problem in a stable family situation.	vs.	Great variation. All the way from profound psychoneurosis to mature, reasonable acceptance of the disability. The impact of the amputation on the socio-economic areas of the patient's existence are generally profound.

with children who have a limb deficiency or amputation of the UE that the prosthesis becomes an aid rather than a replacement (Table 74-9). If the child cannot habilitate to the prosthesis then it will be discarded.

The age at which to fit children with a myoelectric prosthesis is a controversial and complex issue beyond the scope of this chapter. This subject is reviewed in detail elsewhere (12,96,97).

## PROSTHETIC PRESCRIPTION EXAMPLE CASES

The prosthetic prescriptions presented for these cases are as examples only. They do not represent the standard or typical prosthetic prescriptions for these levels of amputation. We want to be clear that a specific prosthetic prescription must be tailored to meet the specific needs of an individual with an amputation. The examples presented here serve to highlight the decision process that might be followed to arrive at an appropriate prosthetic prescription.

### Case 74-1: Transradial Amputation

A 24-year-old, right-handed man sustains a work-related crush injury to his right hand, resulting in a long transradial level of amputation. He plans to return to work operating a drill press.

Possible prosthetic prescriptions include:

- Body power
  1. Double-wall plastic laminate socket
  2. Quick-change locking wrist unit
  3. No. 7 (heavy duty, “Farmer’s hook”) terminal device
  4. Flexible elbow hinges
  5. Triceps pad
  6. Figure-8 harness for suspension
  7. Bowden single-control cable
- External power
  1. Double-wall plastic laminate socket with self-suspending design
  2. Otto Bock Greifer (myoelectric hook) terminal device

In this person, body power will be lightest in weight, most durable, and least expensive. If more than 6 to 7 lb (2.7 to 3.2 kg) of pinch force is necessary from the terminal device for functional activities, the Greifer will provide up to 35 lb of pinch force.

### Case 74-2: Transhumeral Amputation

A 35-year-old, right-handed female homemaker sustains a short transhumeral level of amputation following a motor vehicle accident. Possible prosthetic prescriptions include:

- Body power
  1. Double-wall plastic laminate socket
  2. Constant-friction wrist unit
  3. No. 5XA (lightest weight) terminal device
  4. Internal, alternating locking elbow with turntable
  5. Figure-8 harness
  6. Bowden double-control cable
- External power
  1. Double-wall plastic laminate socket
  2. Otto Bock myoelectric hand
  3. Utah myoelectric elbow
  4. Figure-8 harness

In this woman, because of the short residual limb, external power may be more comfortable and functional but will be heavier and much more expensive than body power.

### Case 74-3: Transtibial Amputation

A 72-year-old-retired man with type II diabetes and PVD has a transtibial amputation for an infected nonhealing ulcer and gangrenous foot. Possible prosthetic prescriptions include:

- Provisional
  1. Total contact PTB thermoplastic socket
  2. Foam liner (soft insert)
  3. Neoprene sleeve suspension
  4. Lightweight alignable shank
  5. SACH foot
- Definitive
  1. Exoskeletal design prosthesis
  2. Total-contact laminated PTB socket
  3. Silicone suction suspension (3-S)
  4. Lightweight multiaxial foot

The provisional prosthesis is a lightweight design that provides a stable support base on which to learn to walk with a prosthesis. The soft liner will make modifications for changes in residual limb volume that are expected to be easier to accomplish. An exoskeletal design with multiaxial foot was chosen for the definitive prosthesis in consideration of the individual’s desire to return to his gardening activities, which required a prosthesis that was more durable and stable on uneven ground with a secure suspension system that would not be torn up when kneeling with the prosthesis.

### Case 74-4: Transfemoral Amputation

A 28-year-old female day care teacher sustained an open comminuted distal femur fracture while mountain climbing and ultimately had a mid-thigh level transfemoral amputation after developing osteomyelitis. Possible prosthetic prescriptions include:

- Provisional
  1. Total contact thermoplastic ICS
  2. TES belt suspension
  3. Hydraulic knee unit
  4. Lightweight dynamic-response foot
  5. Cosmetic foam cover
- Definitive
  1. Total contact carbon fiber, reinforced ischial containment suction frame socket with thermoflex liner
  2. Thigh rotator
  3. Swing and stance phase-control hydraulic knee unit
  4. Split-toe flex-foot
  5. Cosmetic foam cover

The provisional prosthesis, an endoskeletal design with a non-suction socket, belt suspension, and hydraulic knee unit, was chosen to allow easy accommodation for anticipated major changes in residual limb volume that were expected to occur quickly with prosthetic use while at the same time recognizing

this individual's high level of physical activity. The cosmetic cover was added to the provisional prosthesis, not usually done, recognizing her work with small children and her desire not to scare them with the prosthesis. The changes in the definitive prosthesis reflected the individual's desire to eliminate the belt suspension, achieve a more secure suspension, and accommodate her recreational and competitive sports activities. The thigh rotator was added so that she could sit on the floor and work with the children in her class.

### IN MEMORY OF ANDREW J. GITTER, MD (1957 TO 2003)

Dr. Andrew J. Gitter was the initial author of this chapter. Due to his untimely death, he was unable to participate in this revision. The core ideas and proper drawings of prosthetic devices are his legacy to his students and colleagues. Dr. Gitter was appointed as an associate professor at the University of Texas Health Science Center in rehabilitation medicine on February 7, 1997, having previously served on the faculty of the University of Washington Medical School. Dr. Gitter was awarded tenure in September 2001.

Dr. Gitter received his B.S., magna cum laude, in computer engineering from Rochester University in 1979, and he received his M.D., cum laude, from the University of Michigan Medical School in 1980. After completing his residency and an NIDRR Research Fellowship at the Department of Rehabilitation Medicine at the University of Washington, he joined their faculty.

Dr. Gitter was the University of Washington, Department of Rehabilitation Medicine Faculty Teacher of the year in 1991, and in 1999 he was honored as The University of Texas Health Science Center at San Antonio, Department of Rehabilitation Medicine Faculty Teacher of the year. He received the American Board of PM&R Earl C. Elkins Award in 1991 for the highest written board exam score. In 1992, Dr. Gitter won the PM&R Education and Research Foundation Award for best scientific paper published by a physiatrist in practice for less than 5 years, and in 1996 he won the PM&R Education and Research Foundation award for best scientific paper published by a physiatrist in practice for more than 5 years.

Dr. Gitter was the Chief of Rehabilitation Medicine at the Audie L. Murphy Memorial Veterans Hospital and he also served on the staff of Reeves Rehabilitation Center at University Hospital. Dr. Gitter was actively involved with prosthetic research and he was known worldwide for his expertise in gait analysis. He established the first Gait Analysis Laboratory at the Veterans Hospital. Dr. Gitter had an active medical practice and he was particularly revered by his patients from the amputee clinic.

Dr. Gitter is survived by his wife Brenda, and daughters Anna Caitlin, Maria Sofya Catherine, and Yulia Katrina; parents, Richard and Elizabeth Gitter; in-laws, Harlan and Lorena Green; brothers and their wives, Joseph and Linda Gitter, Theodore and Nancy Gitter, Thomas and Karen Gitter; and

sisters and their husbands, Diane and Thomas Mueller, Carol and Kenneth Casolari.

Dr. Gitter was the consummate physician, teacher, researcher, husband, father, and friend. He will be missed by all those who respected and loved him.

# Upper Limb Orthotics

This chapter will enlighten and educate the practicing clinician on the prescription, fabrication, and use of upper limb orthoses. Historically, upper limb orthotic prescription has been complicated by a lack of universal nomenclature, and a variety of methods used to obtain orthoses (e.g., custom-made by an occupational therapist or a certified orthotist, or simply ordered direct from a catalog and fitted to a patient by any medical professional). This chapter will help clarify the common uses and designs of upper limb orthoses, and promote the use of universal terminology for the prescription of these devices.

## DEFINITIONS AND NOMENCLATURE

The term *orthosis* refers to a device that is applied externally to the body to support or improve the function of that body segment. Over the past decade, there has been a strong effort to name all orthoses by the joints they cross, and then specifying any design features related to those joints. Unfortunately, over the past 50 years, upper limb orthoses have been named after the designer or the facility at which they were developed. Better universal terminology would simply include the five common joints of the upper limb including finger, hand, wrist, elbow, and shoulder. The options or control features at each joint could simply be described in a fashion similar to that currently used in lower limb orthotics. The four common options for a joint include fixing the joint in one position, flexion/extension block, flexion/extension traction, and flexion/extension assist. The term “block” refers to a limitation in the range of motion of the joint created by the orthosis. The term “traction” refers to an external force applied across a joint for the purpose of stretching soft tissues (e.g., contracture). The term “assist” refers to an external force applied across a joint to substitute for weak muscles. This is certainly easy to understand as it relates to finger, metacarpophalangeal (MCP) joint, and elbow where we primarily have a hinged joint design. Additional design features will need to describe thumb positioning due to its unique function in opposing the other fingers for both gross grasp and fine motor skills. These design features have been previously described as an opponens bar (for palmar abduction) and C-bar (to maintain first web space). The wrist also requires special attention to address adduction and abduction positioning, or pronation and supination control. The shoulder is a very flexible joint allowing mobility in multiple planes, and potentially leading to challenging nomenclature

for positioning. Fortunately, the vast majority of upper limb orthoses incorporating the shoulder are designed to fix the shoulder in a predetermined position following surgery or trauma. There are upper limb orthoses which stabilize a bony segment following fracture or surgery, but do not cross any joint. These orthoses can be named by the segment involved. All the features described here can be incorporated into a prescription template as shown in Figure 75-1.

All upper limb orthoses can be classified into one of three categories: static, dynamic, or hybrid. *Static orthoses* have no movable joints incorporated into the design. However, a static orthosis may allow active joint motion in one direction, but block motion in another direction (static with block). A static orthosis may also be changed or adjusted to alter the motion allowed or alter the pressure across a joint for stretching purposes (progressive static).

*Dynamic orthoses* have movable joints that can limit motion (block), increase motion through traction, or substitute for weak muscles using supplemental force (assist).

*Hybrid orthoses* will incorporate features of both static and dynamic orthoses into one device. This type of orthosis will cross multiple joints with the intention of limiting or stopping motion at some joints, but allowing or augmenting motion at other joints.

Therefore, a proper prescription for an upper limb orthotic device should include the simple definition of the basic platform by the joints or segments that are involved, followed by special design features controlling each of those joints. The prescription should also include materials for each of these components and any special padding indicated. As with any good orthotic prescription, the diagnosis, disability, prognosis, and duration of need should be indicated on the prescription. There should always be communication between the prescribing physician and the professional who fabricates or fits the upper extremity orthotic device to ensure clear understanding of the goals of the device.

## UPPER LIMB ORTHOTIC GOALS

The primary purpose of all upper limb orthoses, and the rehabilitation program related to their prescription, is to regain or to preserve prehension of the hand. The upper limb is vastly different from the lower limb because of the unique and critical functioning of the hand. The lower limb simply maintains our

**FIGURE 75-1.** Upper extremity prescription template.

body weight as we move through space, and lower limb orthoses primarily prevent us from falling. Conversely, it is the role of the shoulder, elbow, and wrist to position the hand properly in space to provide the essential function of gross motor grasp and fine motor skills. It is the preservation or restoration of this hand function that we strive for with upper limb orthotics. With this in mind, there are five common goals for upper limb orthotics:

1. Substitute for weak or absent muscles
2. Protect damaged or diseased segments by limiting load or motion
3. Prevention of deformity
4. Correction of contracture
5. Attachment of other assistive devices

The first goal is a very common indication for upper limb orthotics. In this case, we *substitute for weak or absent muscles* at the wrist, elbow, or shoulder that fail to properly position the hand, or we substitute for weak musculature within the hand itself that fails to provide proper prehension. Common clinical examples would include cervical spinal injury, brachial plexus injury, or peripheral nerve injury to the median, ulnar, or radial nerves.

The second goal is to *protect damaged or diseased segments* such as those commonly seen in cases of surgical repairs, trauma, rheumatoid arthritis, etc. With trauma or surgical repair, the orthosis is designed to control loading across damaged bony segments or sprained/strained soft tissues, to promote proper healing. This goal is commonly achieved through a series of progressive static or dynamic orthoses, each allowing

increasing loads or movements across a joint. In the case of rheumatoid arthritis and other progressive diseases, such as scleroderma, loads or motions are controlled with the goal of slowing the progression or natural course of the disease. In these conditions, orthoses are also used as an adjunct in pain control when inflamed joints must be temporarily immobilized and then slowly progressed over time.

The third goal of upper extremity orthoses is the *prevention of deformity*. There are many clinical situations of upper and lower motor neuron disease or injury (brain injury, stroke, spinal cord injury, brachial plexus injury, peripheral nerve injury) where proper positioning of the upper extremity is critical to prevent contracture or deformity. In these cases, there is no actual disease or injury to the segment included in the orthosis, but there has been proximal neurological injury creating the risk of deformity or contracture.

The fourth goal of upper limb orthoses is the *correction of contracture*, which may have occurred as a result of disease or immobilization. Very commonly, clinicians are forced to immobilize upper limb segments or joints following a fracture or other significant injury to promote soft-tissue and bony healing. Subsequently, normal range of motion at these joints must be regained through progressive stretching orthoses. This can be achieved through a series of progressive static or dynamic orthoses that are modified on a regular basis. The aggressiveness of the orthotic treatment program is determined by the degree and duration of contracture, and appropriate identification of the soft tissue involved.

The fifth goal of upper limb orthoses is to provide a base for *attachment of other assistive devices*. The simplest example of

this would be a universal cuff, which wraps around the hand to provide positioning of a spoon, fork, or other eating utensils. Universal cuffs have also been commonly used for writing or keyboard devices or other grooming devices. In contrast, the clinician should recognize that the balanced forearm orthosis (BFO) is simply a wheelchair-mounted accessory, which then attaches to a forearm trough. The BFO provides enormous assistance to the patient with spinal cord injury to carry out activities of daily living (ADLs), such as feeding, grooming, and even access to household technologies (light switch, telephone, television remote control).

## BIOMECHANICAL PRINCIPLES

There are five critical concepts that must be understood to appreciate the proper design and fabrication of upper limb orthoses. Failure to understand and integrate these principles into the upper limb orthosis may produce less than optimum functional outcome or even injury to the patient. The five principles include:

1. Three-point control concept
2. Tissue tolerance to compression and shear forces
3. The biomechanics of levers and forces
4. Selection of materials
5. Static versus dynamic control

The *three-point control concept* is the basis of nearly all upper and lower limb orthotic designs (Fig. 75-2). Generally, a strong force is applied at a joint and a counterforce applied proximal and distal to that joint. The location of the force and counterforce may be clearly identified as a specific loop or bar in the orthotic design. However, in many instances the force and counterforces may be obscurely hidden into the design of the orthotic device. The precise point of application and the magnitude of the force and counterforce are critical to achieve the goal of controlling that joint.

**FIGURE 75-2.** Three-point control concept. A strong force is applied at a joint to control motion, and a counterforce is applied proximal and distal to the joint.

The *tissue tolerance to both compressive and shear forces* must be understood if the orthosis is to be designed and fabricated safely. There are more than 30 pressure-sensitive bony prominences in the wrist, hand, and fingers alone. Avoiding prolonged, excessive pressure over these bony prominences will preserve skin integrity and patient comfort. Pressure duration curves adopted from other rehabilitation fields (such as seating systems) have indicated that higher pressures of 100 to 300 mm Hg are tolerated for only 2 to 4 hours continuously, whereas lower pressures of 20 to 50 mm Hg are tolerated for up to 12 hours a day continuously. If high pressures are anticipated at a joint or bony prominence, then a proper wearing schedule should clearly delineate the duration of time and the frequency of use throughout the day or night. Although a longer stretching time will reduce a contracture more rapidly, the risk of skin breakdown increases steadily with wearing duration. The clinician should also remember that distribution of pressure over a larger surface area is better tolerated than a small focused pressure. It is also important to remember the natural position of the transverse and longitudinal arches of the hand, especially in static positioning orthoses.

The *biomechanical forces* applied in upper limb orthotics are most analogous to a class one lever, commonly known as a seesaw. Most individuals recognize that a seesaw has a force applied at both ends with a central fulcrum. Rehabilitation specialists should also understand that a relationship exists between the magnitude of the pressure applied (force) and the distance to the fulcrum (lever). In essence, the farther from the fulcrum or from the joint, the less pressure needed to generate a fixed force across the joint. If tissue tolerance is a concern due to the required magnitude of pressure, one can simply move the point of pressure application farther from the joint to decrease the magnitude of the applied pressure. In other words, by increasing the lever distance, less pressure can generate the same force across the joint (Fig. 75-3). The angle of pull of force is also very important to produce effective control of the identified joint, and to prevent damage to collateral ligaments. If the angle of pull is not perpendicular to the joint, the orthosis may overstretch collateral ligaments and create mediolateral instability at the joint. As an example, stretching a flexion contracture across the MCP joint or interphalangeal (IP) joint requires a direction of pull perpendicular to the finger. If the pull is at an

**FIGURE 75-3.** Lever force. Less force is needed with a longer lever distance.

**FIGURE 75-4.** Traction angle. The angle of pull is correct on the index finger, but incorrect on the middle finger, because it is not perpendicular to the MCP joint.

angle to the finger, then less effective stretching of the flexor tendon is achieved and unwanted stretching of collateral ligaments may occur (Fig. 75-4). The clinician must also understand that forces will impact the design of the device and help determine the materials that will be used to provide structural stability to the orthosis. For example, a long outrigger attached to a small platform on the dorsum of the hand may provide an inadequate base of support and lead to bending or deformity of the outrigger or the orthosis. A more stable outrigger and longer base of support will provide good biomechanical stability to the orthosis and provide the adequate stretch necessary.

The *selection of materials* for upper limb orthoses depends on the flexibility, strength, and durability of the material necessary to achieve the proper outcome. Most upper limb orthoses are fabricated of thermoplastics for the structural design. Low-temperature thermoplastics are commonly used because they can be easily shaped or formed to the patient's limb without the need for high-temperature ovens. They can also be easily modified by a common heat gun. However, these devices may also deform under exposure to common heat sources such as the sun or radiators. High-temperature thermoplastics may be indicated for certain longer-term or high-stress devices. Various metals are still used for parts of upper limb orthoses where a lightweight, strong, and compact design is indicated. This includes aluminum frames, joints, and spring wire materials. Ultimately, carbon fiber materials can be used for very strong and very light designs, but manufacturing these orthoses requires specialized equipment and training. Foam materials are commonly used as padding to improve tissue tolerance in high-pressure areas.

Finally, the overall biomechanics of any upper limb orthosis can be defined as static, dynamic, or hybrid. A traditional static orthosis will simply stabilize or fix one or multiple joints. Generally, a static positioning splint for a flaccid limb will create very low tissue pressures and very low forces at joints. This is tolerated well and can be worn nearly continuously without concern of skin breakdown. However, static positioning splints

for an upper limb with an increased tone will certainly generate much higher tissue pressures and the design should incorporate additional padding in these situations. A wearing schedule is also much more important when increased tone is encountered. A dynamic orthosis allows or enhances movement across a joint. Dynamic orthoses generally have fairly low tissue pressures unless external forces are applied such as stretching of a contracture, or in the case of an abnormal increased tone from upper motor neuron injury. In cases of a dynamic orthosis with an external force applied, the biomechanical stresses within the orthosis and the tissue compression will be high.

## ANATOMICAL PRINCIPLES

Proper upper limb positioning requires an understanding of multiple anatomical issues, particularly when a joint is to be immobilized. The wrist should be immobilized in slight extension and neutral pronation/supination. This position facilitates hand prehension activities to reach the face and midline trunk for ADLs.

The IP joints of the fingers should be immobilized in extension, but the MCP joints should be immobilized in flexion to maintain the length of the collateral ligaments. The IP and MCP joints should be mobilized as soon as possible to prevent contracture and adhesions of the long flexor and extensor tendons.

The thumb should be immobilized opposite the fingers in palmar abduction and extension. The web space should be maximized to maintain both gross grasp and fine motor pinch (Fig. 75-5).

The hand itself has two transverse arches (proximal and distal metacarpals) with two different radii. These arches must be preserved to maintain proper finger positioning. As each finger is flexed individually, its fingertip points to the scaphoid bone, because of the distal arch. An orthosis that provides traction in finger flexion must also follow this same angle to the

**FIGURE 75-5.** Proper positioning of the wrist, hand, and finger when immobilized. (Courtesy of North Coast Medical.)

scaphoid. As mentioned earlier, traction across a finger or any segment should be perpendicular to that segment and follow the anatomical angle of the joint involved.

## COMMON UPPER LIMB ORTHOTIC DESIGNS

### Finger and Thumb Orthoses

Simple static orthoses for the fingers or thumb are commonly used to treat fractures, collateral ligament sprains, and burns of the digits. These can be partial or complete circumferential designs providing both flexion-extension control and medio-lateral stability across the IP joints. Static positioning of the IP joints should be in extension to maintain the full functional length of collateral ligaments. Static finger orthoses with a flexion or extension block allow motion in one direction, but not the other. The best example of this is the finger ring orthoses, commonly used in rheumatoid arthritis (Fig. 75-6). The boutonniere's deformity creates flexion at the proximal IP (PIP) joint and hyperextension at the distal IP (DIP) joint. This can be controlled using the ring orthoses to block flexion at the PIP joint. The swan-neck deformity causes hyperextension at the PIP and flexion at the DIP joint. The same ring orthoses can be reversed to encourage flexion and block extension at the PIP. A variety of dynamic orthoses across the IP joints of the fingers are used for the purpose of stretching flexion contracture at the IP joint (Fig. 75-7). Traction is placed across the contracted joint using spring wire or rubber bands. A progressive static orthotic program can accomplish the same result with regular adjustment or alteration of a static orthosis to stretch the contracture across an IP joint. This can be accomplished through tightening of the screw, adjusting of a thermoplastic design, or altering a Velcro strap (Fig. 75-8).

### Hand-Finger Orthosis

The most common reason for fabricating hand-finger orthoses is to gain control of the MCP joint of the fingers

**FIGURE 75-7.** Dynamic finger orthoses. (Courtesy of North Coast Medical.)

or thumb. Historically, the traditional static hand-finger orthosis consisted of a short opponens orthosis fabricated from metal, which wrapped around the medial or lateral side of the hand, preserving the arch of the hand. This would then act as a platform for outriggers or additional features, which would control the thumb, the MCP joints, or the fingers. A traditional short opponens orthosis would include a C-bar to maintain the web space between the thumb and the other fingers, and an opponens bar to position the thumb opposite the fingers for gross grasp and fine motor pinch (Fig. 75-9). This is most commonly used for median nerve injuries where control of the thumb and opposition are lost. An MCP extension block can also be incorporated into this orthosis to prevent MCP hyperextension (claw-hand deformity) which occurs in both median and ulnar nerve injuries. This modification allows the remaining intrinsic hand muscles to function as effectively as possible. The same short opponens design can be replicated using plastics with a circumferential design to

**FIGURE 75-6.** Static finger ring orthosis. (Courtesy of North Coast Medical.)

**FIGURE 75-8.** Progressive static finger orthosis. (Courtesy of North Coast Medical.)

**FIGURE 75-9.** Opponens orthosis metal design with C-bar and opponens bar to stabilize thumb.

maintain the transverse arches of the hand, place the thumb in opposition, and act as a platform for other attachments (Fig. 75-10). The term “thumb spica” refers to a hand-finger orthosis, which is based on the hand and extends circumferentially around the thumb to fix the thumb in opposition (Fig. 75-11). This is most commonly used for inflammatory conditions affecting the thumb such as rheumatoid arthritis, or de Quervain’s tenosynovitis, as well as for osteoarthritis. This can also be used for fracture of the first metacarpal to maintain the thumb in a functional position. Other static hand-finger orthoses are commonly used for rheumatoid arthritis to control or prevent MCP subluxation and ulnar drift (Fig. 75-12). These would still allow long flexor and extensor tendons to activate finger control while maintaining stability at the MCP joints.

Dynamic hand-finger orthoses are most commonly used for flexion or extension contracture across the MCP joints. The three-point control concept is again used with a force

**FIGURE 75-11.** Thumb spica. (Courtesy of North Coast Medical.)

applied close to the MCP joint and opposing counterforces proximal and distal. The common “knuckle-bender orthosis” is used to stretch the extension contracture at the MCP joints when collateral ligaments have been allowed to shorten due to immobilization (Fig. 75-13). Dynamic hand-finger orthoses can also be used for more vigorous stretching of flexion contracture at the PIP joints. These orthoses would incorporate a thermoplastic circumferential platform at the hand with attachment of MCP block to prevent hyperextension, and an outrigger to create an extension stretch across the PIP joint (Fig. 75-14). Once again, it is important to remember that the direction of pull must be perpendicular to the segment and that the angle of pull must follow the joint motion. As the flexion contracture improves, the positioning of the outrigger must be adjusted to accommodate for this change. Failure to provide MCP extension block may simply create hyperextension across the MCP and failure to stretch the PIP contracture.

**FIGURE 75-10.** Plastic short opponens. (Courtesy of North Coast Medical.)

**FIGURE 75-12.** Hand-finger orthosis. Plastic design to control MCP subluxation in rheumatoid arthritis. (Courtesy of North Coast Medical.)

**FIGURE 75-13.** “Knuckle-bender” orthosis. Dynamic design to promote flexion at the MCP joint. (Courtesy of North Coast Medical.)

### Wrist-Hand-Finger Orthosis

Today, static wrist-hand orthoses are most commonly used for the treatment of carpal tunnel syndrome. This orthosis includes wrist positioning in neutral (i.e., 0 degrees of extension) and allows full freedom of thumb and finger movement (Fig. 75-15). Carpal tunnel syndrome commonly results from the overuse of the wrist and hand causing inflammation within the carpal tunnel. Therefore, immobilization of the wrist for part or all of the day and night often helps to resolve symptoms. Other uses of static wrist-hand orthoses include traumatic wrist sprain, or wrist inflammation due to diseases such as rheumatoid arthritis. Static wrist-hand-finger orthoses are also commonly used as the first step following injury or repair to flexor or extensor tendons of the hands. A short period of immobilization is often followed by limited motion to prevent adhesions of flexor and extensor tendons, and joint contracture. With flexor tendon repair, the wrist is commonly positioned

**FIGURE 75-15.** Static wrist-hand orthosis. (Courtesy of North Coast Medical.)

in neutral or flexion position. The MCP joints are blocked in flexion and the IP joints may be allowed to go to full extension. Often, flexion traction is applied across the fingers to promote a protective positioning of the finger and eliminate tension across the repair (Fig. 75-16). As healing progresses, the MCP block is eliminated to allow further motion without allowing full extension at the wrist until the repair is completely healed. The wrist-hand-finger orthosis for extensor tendon repair includes a similar but contradictory design where the wrist is positioned in a static manner at neutral or extension position with a flexion block at the MCP and IP joints of the involved fingers. Often extension traction is applied across the MCP and IP joints to alleviate tension across the repair site (Fig. 75-17). As healing progresses, further flexion is allowed at the MCP and IP joints. Finally, full wrist flexion is allowed once healing is complete.

**FIGURE 75-14.** Dynamic wrist-hand-finger orthosis with MCP block and active extension stretch across PIP joints using an outrigger. (Courtesy of North Coast Medical.)

**FIGURE 75-16.** Dynamic wrist-hand-finger orthosis with extension block at MCP joint and fingers, and dynamic traction at the index finger. (Courtesy of North Coast Medical.)

**FIGURE 75-17.** Dynamic wrist-hand-finger orthosis with flexion block at MCP joint and fingers, and traction at fingers.

Radial nerve injury also often requires a wrist-hand-finger orthoses to assist wrist and finger extension. This is accomplished with dynamic orthoses, with rubber bands or spring wire providing extension at the wrist and outriggers with rubber bands providing extension at the fingers. An outrigger or C-bar must also be incorporated to maintain the thumb in opposition (Fig. 75-18).

The tenodesis prehension orthosis or flexor hinge orthosis is a dynamic wrist-hand-finger orthosis incorporating active wrist extension movement to regain gross grasp and fine motor pinch of the thumb and fingers. This is used in C6-level quadriplegia where some wrist extension strength is maintained with little or no long finger flexor strength or intrinsic muscle strength of the hand. The Rehabilitation Institute of Chicago design incorporates a non-elastic cord, which crosses the wrist, hand, and MCP joint to facilitate three-jaw chuck pinch with active wrist extension (Fig. 75-19). The more traditional, and

**FIGURE 75-18.** Dynamic wrist-hand-finger orthosis with stabilization of the wrist and extension of the fingers and thumb following radial nerve injury. (Courtesy of North Coast Medical.)

**FIGURE 75-19.** Dynamic wrist-hand-finger orthosis using Rehabilitation Institute of Chicago design for prehension. (Courtesy of North Coast Medical.)

more elaborate, flexor hinge design uses an adjustable rigid rod that facilitates prehension. The size of the opening of the hand is adjustable through changes in the length of the rigid rod (Fig. 75-20).

Finally, simple static wrist-hand-finger orthoses can be used for positioning of the hand following stroke, brain injury, or brachial plexus injury. As mentioned previously, the MCP joints should be positioned near full flexion and the IP joints in full extension to prevent contracture of the collateral ligaments. The thumb should also be positioned opposing the fingers and maintaining the web space (see Fig. 75-5).

### Elbow Orthoses

Dynamic elbow orthoses are commonly used for flexion or extension contracture across the elbow due to immobilization. If burn scars are involved, this should include total contact across the burn scar area for compression treatment of the

**FIGURE 75-20.** Dynamic wrist-hand-finger orthosis with traditional metal flexor hinge design.

**FIGURE 75-21.** Dynamic elbow orthosis. (Courtesy of North Coast Medical.)

burn. Various spring-loaded elbow orthoses are commercially available, which can be easily adjusted by the patient or therapist to steadily increase tension across the elbow as stretching progresses (Fig. 75-21). Spring-assisted elbow orthoses are also used to augment elbow flexion when weakness or paralysis of the biceps muscle exists. Static circumferential orthoses across the elbow are often used for fractures at or near the elbow. Fractures of the radius and ulna should incorporate the elbow, wrist, and hand to control pronation and supination. An adjustable lock, such as the dial lock, can be incorporated into the elbow-wrist-hand orthosis to steadily progress motion at the elbow in flexion or extension, and still control pronation and supination (Fig. 75-22). Humeral fracture management may include a circumferential orthosis across the entire humeral segment and forearm. This would initially start as a static orthosis and slowly progress movement at the elbow as healing of the humeral fracture occurs.

### Shoulder Orthoses

Flexible arm slings of various sorts have been used for a variety of problems including clavicular fracture, acromioclavicular

**FIGURE 75-22.** Elbow-wrist orthosis with adjustable lock at elbow and controlled motion at wrist.

**FIGURE 75-23.** Flexible shoulder orthosis used to control humeral subluxation. (Courtesy of North Coast Medical.)

joint injury, proximal humeral fracture, and glenohumeral subluxation due to hemiparesis. These do not clearly fit into the categorization of static or dynamic design due to their inherent lack of identifiable joints or rigid design features. These orthoses commonly consist of fabrics and straps that encompass the mid- to proximal humerus, and then extend across the shoulder anteriorly and posteriorly to the opposite axilla (Fig. 75-23). The primary goal is to maintain glenohumeral integrity and to limit motion across the AC and glenohumeral joints. A true static shoulder-elbow-wrist-hand orthosis, such as the airplane splint or arm abduction orthosis, can prevent movement across the glenohumeral joint by stabilizing the arm in abduction (Fig. 75-24). This is done for shoulder dislocation, shoulder surgery (e.g., rotator cuff repair), and some proximal fractures. Care must be taken to mobilize the glenohumeral joint as soon as possible to prevent adhesive capsulitis.

Other specialized orthoses in this category include the BFO for patients with C5-level spinal injury. This device

**FIGURE 75-24.** "Airplane splint" for static humeral abduction positioning. (Courtesy of North Coast Medical.)

**FIGURE 75-25.** Universal cuff with fork inserted.

includes a forearm trough which is suspended on a series of brackets and swivels mounted on the wheelchair. This eliminates the weight of the arm and allows the patient to use elbow flexion and shoulder adduction/abduction for feeding and limited ADLs. A universal cuff or hand orthosis is used to attach a swivel spoon or other device, which would then allow independent feeding by the patient (Fig. 75-25). Finally, a combination of prosthetic and orthotic components can be used for the patient with brachial plexus injury to create a shoulder-elbow-wrist-hand orthosis to regain some limited prehension at the hand once the elbow is locked and stabilized. A dual control cable to a figure-8 harness can use bicipital abduction to position the elbow and activate a prehension orthosis at the wrist and hand when there is complete paralysis at the elbow and hand. If the hand is not usable due to contracture, then a prosthetic hook can be applied at the palmar surface of the hand to obtain prehension (Fig. 75-26). The elbow can be locked in place using an additional strap which is activated with shoulder movements or by reaching across with the opposite hand. The paralyzed limb can then be used as a helper or stabilizer for the remaining functional arm.

## EMERGING TECHNOLOGY

The concept of neural integration has recently been incorporated into upper limb orthoses. Commercially available devices are now being used to create prehension or gross grasp in the paralyzed limb. These devices detect a myoelectric signal from an intact proximal muscle, and then send a signal to distal paralyzed muscles. The paralyzed muscles are stimulated to contract via surface-based electrical stimulation. Stimulating electrodes over the finger flexor and extensor muscle groups create grasp and release maneuvers. The orthotic device itself supports the wrist as a wrist-hand orthosis.

The usefulness of these devices is variable, and is dependent upon physical factors such as muscle tone, target muscle excitability, and the presence of contractures. Good strength at

**FIGURE 75-26.** Shoulder-elbow-wrist-hand orthosis with prosthetic hook for prehension.

the shoulder and elbow greatly enhances the functionality of these devices.

As can be seen, most common upper limb orthotic designs can be appropriately described using universal terminology and a prescription template, rather than abstract names. Any new or unique design features or materials can be added to this same template. Communication between the prescribing physician, patient, and therapist/orthotist will ensure fabrication and fit of a proper upper limb orthosis. Adequate instruction to the patient, and appropriate therapy and follow-up will help to prevent complications and achieve a favorable outcome.

# Lower Extremity Orthotics, Shoes, and Gait Aids

Lower limb orthoses, with their many variations, are among the most commonly prescribed biomechanical devices intended to assist walking in individuals with gait dysfunction, caused by musculoskeletal or neuromuscular diseases, (1). Walking is one of the most desirable self-reported goals for patients entering a rehabilitation program and the preponderance of lower limb orthotic devices in clinical use reflects this desire and the fact that present orthotic technology often does a reasonable job of restoring gross physical capacity for level walking and standing.

## ROLE AND USE OF ORTHOTICS

Orthoses are devices applied to the external surface of the body to achieve one or more of the following; relieve pain, immobilize musculoskeletal segments, prevent or correct deformity, and improve function. Orthoses provide a direct support component to the braced limb segment and limit the range of motion of a joint. This mechanism largely gives rise to reduction of axial loads and thus perhaps aids in joint pain relief. It may also be used to partially or fully immobilize the joint, and in this manner produce deformity prevention or correction and also improve function. In conjunction with the above two mechanisms, a more difficult mechanism to visualize is the fact that orthoses modify the total static and dynamic force/moment distributions in the braced and more distal segments ("in" joints or about a joint center) and provide a substitute power source for weak muscles while maintaining level surface walking safety and efficiency.

Overall, orthotics can be divided into two major categories, namely, corrective and accommodative devices. In the near future, orthotic technology will also provide artificial strength. Corrective devices are meant to improve the position of the limb segment, either by stretching a contracture or correcting the alignment of skeletal structures (1). Accommodative devices are meant to provide additional support to an already deformed tissue, to prevent further deformity, and ultimately to improve function. Orthoses can be further classified as static (resting) or dynamic, the latter permitting movement of the involved joint(s) while controlling the direction or alignment of the movement and, at times, providing a substitute power source for weak muscles. The spectrum of orthotic devices

available is quite broad, ranging from a simple plastic device applied across one joint to a much more complex device made of a variety of materials and crossing multiple joints (2), some also include control microprocessors. Knowledge of the disease or disorder being addressed with an orthosis, functional anatomy, biomechanics, orthotic components, materials, and, finally, recognition of the anticipated functional outcome are essential for proper orthotic prescription (3,4).

## TERMINOLOGY

In the past, the lexicon of terms used to describe orthoses was very confusing; often, clinicians used different terms to describe even the most basic device. Orthoses or parts of devices were given names that might describe their purpose, the body part to which they were applied, the inventor of the device, or the town or institution where they were developed. To facilitate communication and minimize the use of acronyms, a logical, easy-to-use system of standard universal terminology for orthotic devices was developed in the early 1970s by the International Committee on Prosthetics and Orthotics (3). Orthotic devices are named by the joints they encompass in correct sequence followed by the word orthosis. For example, an orthosis that crosses the ankle and the foot is named an ankle-foot orthosis (AFO). One that crosses the knee, ankle, and foot is called a knee-ankle-foot orthosis (KAFO). The intended biomechanical function or material may complement the terminology (i.e., dorsiflexion assistance plastic AFO). More elaborate names or eponyms are typically given to such devices (3), but such language should be avoided whenever possible.

## MATERIALS

The orthotic components chosen depend on the functions they fulfill, but most orthoses consist of three basic elements: interface components, structural components and if intended to be articulated, the type of joints. In orthoses of newer design, it may be impossible to differentiate the joints from the structural and interface components, for example, plastic AFO (2).

**FIGURE 76-1.** Example of an orthotic prescription form.

The choice of materials in the fabrication of orthotics is expanding rapidly, and a full review of them is beyond the scope of this chapter. The reader is encouraged to expand knowledge on the subject by reading elsewhere about this topic (5). The two primary material categories are plastics and metals. Plastics have the benefits of light weight, total contact, adjustable flexibility, the ability to adjust in shape, and a more cosmetic appearance. Metal orthoses often have the advantage of increased durability and, in the hands of a skilled orthotist, built-in adjustability. With the advent of new products such as carbon graphite and extruded plastic materials, the advantages of maximal tension strength, lightweight design, and ease of adjustability are

combined (6). Factors that dictate the type of material used in orthotic fabrication include the length of time the orthosis will be used, the amount of forces applied across the orthosis, and the amount of axial weight loading. A complete orthotic prescription should include the joints it encompasses and suggest the desired biomechanical alignment and materials of fabrication and materials to use for closures (e.g., leather straps, Velcro, etc.), and where they should be attached (Fig. 76-1).

When the orthosis is ready, it should be evaluated off and on the patient to ensure proper construction, fit, and function. When these characteristics are achieved, appropriate training of the patient and family should be organized.

Orthotic management is best accomplished in the majority of patients with the use of plastic molded orthoses. They provide more intimate contact with better distribution of the controlling/corrective forces over a larger surface area. These devices generally fit inside the shoe, tend to be more cosmetic, and hence better accepted. The patient is permitted to exchange shoes as long as constant heel height is maintained to avoid altering the intended dynamic alignment of the device. Plastic materials are lighter in weight and easier to maintain. The recent availability of adjustable ankle joints that can be attached to plastic orthoses has eliminated a major disadvantage of these devices when compared to metal/leather device. Lack of sensation and fluctuating edema are relative contraindications to the prescription of plastic molded devices. If the patient has adequate visual perception, cognition, and good social support, he or she can compensate for these two deficits and receive the added benefits provided by plastic braces. Two major types of plastic materials are used in orthotics: thermosetting and thermoplastic. Thermosetting plastics include formaldehyde, epoxy, and polyester resins that are typically used as laminates in a similar manner than that used for prosthetic socket fabrication. They require heat produced by a chemical reaction to harden a multilayer of weaved fibers of different products but do not soften with subsequent heating.

Thermoplastics soften when they are heated, making the material moldable. Subsequent heating will soften the material for further molding, and lowering the temperature hardens the material once again. High-temperature thermoplastics, such as polyethylene, polypropylene, copolymers, ortholene, thermoplastic elastomers and vinyl polymers, require heating to temperatures greater than 150°F to mold. Fabrication of an orthosis made of any of these materials requires an exact plaster mold of the desired body part. The heated plastic is then applied to the replica for proper molding under vacuum. These materials are durable, and they have a “good elastic memory,” returning to their original position after flexible deformation. Adjustments to the biomechanical alignment and fit of an orthosis require the intervention of an orthotist. Based on the trim lines of the material, orthosis provide support and may also give a spring-action force (Fig. 76-2).

Metal/leather orthoses continue to have a definite place in the treatment of many patients such as those with fluctuating edema, soft tissue wound, hyperhydrosis or intolerance to plastics. Traditional orthotic devices use metals to provide strength and durability. Straps and padding are made of leather. The metals primarily used are steel and aluminum, mostly in alloy forms with various other metals to further increase their strength and to resist corrosion. Although metal orthoses are heavier and are cosmetically less appealing to many patients, their durability and adjustability allows them to accommodate for longitudinal growth and the changing needs of the patient (Fig. 76-3). The choice of orthotic material depends on the clinical purpose and the clinical characteristics of the patient.

Proper biomechanical alignment of any orthosis is critical to maximize the ambulatory capability of a patient. Biomechanical malalignment can and does prevent a borderline

**FIGURE 76-2.** Plastic AFO.

patient from becoming a functional ambulator; those patients with better recovery or less deficit may be able to compensate for inadequate orthotic alignment. In those patients for whom orthotic joint motion is required, close correlation between the orthotic and the anatomic joint centers of rotation is mandatory to avoid a discrepancy in the axis of motion which could likely produce pain, joint swelling, skin breakdown, and other preventable problems.

Adjustability of alignment is a significant advantage to current practice patterns where patients are transferred to inpatient rehabilitation programs much earlier than in the past, and the length of stay in the rehabilitation programs has decreased significantly. Predicting the final rehabilitation outcome of these patients so early in their recovery may be very difficult. The ability to adjust the biomechanical alignment of the orthosis with simple tools or to convert a controlling force into an assistive one in order to respond to the patient's needs

**FIGURE 76-3.** Metal AFO.

is an important advantage. This is also a potential risk as individuals or patients without the needed knowledge may alter the alignment of the brace or simple use over time may loosen the components (2).

## THE SHOE

The shoe is an integral part of any lower limb orthosis that includes the foot, as it serves as the foundation for the device and directly impacts its function (7). The basic function of the shoe is to protect the foot from rough walking surfaces, the weather, and the environment and to provide support for the feet during standing and walking. The use of properly fitting shoes is absolutely essential to the success of any foot orthosis or AFO (8). Factors to consider when selecting a shoe are size, shape, fit, and function. Proper shoe size must take into consideration fit while standing, as the foot configuration changes with weight bearing and pathological phenomenon such as spasticity (9). The foot may swell with prolonged sitting or activity and is often best fitted at the end of the day and after walking around. If a plastic brace is used, then the shoe may need to be slightly longer and or wider to accommodate for this. The parts of a shoe consist of the sole, the heel, the counter (heel and longitudinal arch), the upper, the linings, and reinforcements (10).

Each shoe component can be made of a wide variety of materials and designs, depending on the quality and specific use. It is often best to use flexible, breathable materials such as leather and canvas and not synthetic (plastic) materials for the shoe's upper components. The construction material of the shoe is very important when considering the function and the modifiability of a shoe. Many off-the shelf shoe styles are available and most can be modified, thereby limiting the need for custom shoes reducing cost and increasing cosmesis resulting in better compliance.

Shoes are built around a positive model or replica of the weight-bearing foot, which is called a last (11). The last, which is made of solid rock maple or plastic materials, determines the fit, walking comfort, appearance, and style of the shoe. Usually the last has a slight fore foot in-flare. Other common lasts include the broad-toe last with a straight medial border that extends from the heel to the toe; the juvenile symmetric straight last, which can be bisected into nearly equal right and left halves; and the orthopedic last with special features designed to accommodate various structural and anatomic problems (e.g., varus, valgus).

During fabrication, the insole is nailed to the last, the lining is tucked to the inner sole rim, and the reinforcements (i.e., counter, toe box) are attached. The upper of the shoe is softened by humidity for easier molding and fitted snugly to the last to conform to its every detail and then nailed or glued to the inner sole. Finally, the outer sole and heel are attached. The Goodyear welt construction of shoes is a method used in production of high-quality shoes in which the upper is sewn to the sole. This method provides a perfectly smooth inner surface, comfort, and a strong shoe that retains its shape and is easy to modify and repair. Unfortunately, these shoes tend to be bulky, heavy, and less flexible.

The upper is that part of the shoe that is above the sole. It is most commonly made of leather, although any soft and durable material may be used. Leather is found to be most comfortable because it allows evaporation and absorption of moisture and molds well to the shape of the foot. Deerskin is significantly softer than leather. It stretches more easily and is generally more accommodative, but is not nearly as durable as leather.

Upper materials are important because they affect the comfort and fit, and performance and durability of the shoe. Shoe uppers are also frequently made of man-made materials such as fabric, nylon, canvas, and plastic but in general they are more difficult to stretch or modify. Recently heat moldable uppers and other elastic plastic materials (e.g., neoprene) have been introduced to the fabrication of shoes. The material is capable of easily stretching around anatomical deformities such as bunions or hammer toes but a problem with this material is its reduced capacity to dissipate heat and moisture. They are an especially useful alternative to custom shoes in patients with severe fore foot deformities who otherwise would need costly custom shoes.

The upper consists of the vamp, quarters, and lace stay. The vamp is the anterior portion of the upper, which covers the toes and the instep. The tongue, a strip of leather lying under the laces, and the throat, the opening at the base of the tongue, are parts of the vamp. Anteriorly, the vamp has a reinforced toe box or toe cap to maintain appearance and to protect the toes against trauma. The lace stay or the portion containing the eyelets for laces is usually part of the vamp, but it may also be part of the quarters. The two quarters make up the posterior part of the shoe. The quarters are usually reinforced by the heel counter, which stabilizes the foot by supporting the calcaneus and giving structural stability to the

**FIGURE 76-4.** Shoe types and styles. **A:** Oxford or low quarter. **B:** Blucher-type Oxford. **C:** Bal-type Oxford. **D:** Chukka or high quarter. **E:** Pump. **F:** Moccasin. **G:** Sandal. **H:** Child's shoe.

shoe. The counter usually extends anteriorly to the heel breast, but it may extend further forward or upward on specially designed shoes. Similar to the toe box, the counter is made of firm leather or synthetic material. Sometimes a band of leather, referred to as a collar, is stitched to the top of the quarters to reduce foot pistoning and to stiffen the shoe. Laterally, the quarter is cut lower to avoid infringing on the malleolus. The linings are made of leather, cotton, or canvas and should be used in all portions of the shoe that are in contact with the foot to absorb perspiration and smoothen the contact area, thus providing added comfort.

The heel of the shoe is attached to the outer sole under the anatomic heel and is made of leather, wood, plastic, rubber, or metal. The heel block, which is fastened to the heel seat, is made of a firm material, but the plantar surface is usually made of hard rubber. The anterior surface of the heel is called the breast. The height and design of the heel vary greatly. Its height is measured at the breast. The flat heel has a broad base and measures 0.75 to 1.25 in. (2 to 4 cm) in height. A Thomas heel is a flat heel that has a medial extension to support a weak longitudinal foot arch. Heels up to 3 in. (7 cm) high are available, but they are mainly used for fashionable appearance rather than for extended walking. Shoes with lower heels, no heels, or negative heels popularized by the earth shoe also exist.

The clinician needs to be aware that the height of the heel has a direct impact on the foot and ankle positions and affects the proximal joints and general posture of the trunk. When a brace is manufactured and aligned, this is done with a particular shoe heel height as part of the design (4). High heels, especially those with a tapered, narrow striking point, make the ankle and foot more unstable and thereby contribute to foot stress, ankle injuries, and falls. Some studies have linked the use of such shoes to abnormal forces in the more proximal joints (12).

### Types and Styles

There are innumerable shoe types and styles, although basic designs are relatively few (Fig. 76-4). The basic designs are determined mainly by the shape of the upper, particularly the design of the toe and the height of the quarters. The low-quarter shoe, also known as Oxford shoe, is characterized by the quarters finishing approximately 1 in. below the malleoli with no restriction of ankle or subtalar movement. In high-quarter shoes, the quarters may extend up to barely cover the malleoli, as in the chukka shoe, or extending to the lower third of the tibia or higher, as in boots. This style prevents piston action during walking and back-and-forth sliding of the foot. In addition, it provides some degree of medial-lateral stability at the ankle and subtalar joints, and some restriction of plantar/dorsiflexion ankle motion. The most common opening style is the blucher type, in which the lace stay is not directly fastened to the vamp. This style gives a wide opening for the foot for easy insertion and greater adjustability over the mid foot. For ease of access the surgical opening shoe allows exposure of the entire foot by opening up to the toes. The bal-type (Balmoral) throat, which has the face stay attached directly to the vamp, does not provide such easy foot access. Shoe closure usually is accomplished by cotton laces, which thread through two or more pairs of eyelets, although closure can also be achieved by buckles, zippers, Velcro flaps, or elastics.

Modifications to commercial footwear and in some instances, custom footwear are an important aspect of orthotic practice. Shoe modifications can successfully treat many simple problems that affect walking and is an integral part of any orthotic prescription (11,13).

Dozens of base materials and literally hundreds of variations of those base materials are used in the manufacture of shoes. In this section, discussion is limited to the general categories of materials found in shoes used in conjunction with orthosis and with or as corrective devices. The shoe can be

**FIGURE 76-5.** A: Athletic shoe. B: Drawn request for shoe modifications.

modified by adding a variety of alterations including changes to the heel, the addition of metatarsal pads, rockers, and other modifications.

### Sole Materials

Materials used in the construction of shoe soles vary greatly and have significantly different properties with regard to weight, durability, shock absorption and attenuation, flexibility, and support.

Leather soles are extremely durable and once it was the choice soling material but now it is reserved primarily for high-end dress shoes. Leather tends to be stiff and heavy, and offers little or no shock absorption when compared to other materials and can be slippery in wet conditions. Leather soles do allow for relatively simple attachment of AFOs.

Hard rubber is a great alternative to leather, especially when used to attach an AFO as it has some degree of impact absorption at heel strike and it is less slippery when used to walk in wet environments. Crepe is a cellular rubber compound that typically offers a great combination of shock absorption and traction. A shoe with a crepe sole can still have an AFO attached to it, although it is not as easy as with a leather or rubber-soled shoe to fabricate. Crepe is the most commonly used material for shoe modifications.

Vibram® is a dense microcellular rubber. It has many qualities of crepe but is more durable and can be more shock absorbing. This material can also be used with a shoe in the construction of an AFO.

Ethylene vinyl acetate (EVA) is a more recent introduction in the industrial manufacture of most types of shoe. It is shock absorbing, moldable, lightweight, and flexible and can have a multitude of colors. Sometimes this material can be difficult to use in AFO fabrication due to lack of adherence to commonly used cements. In recent years athletic shoes (Fig. 76-5A) have changed dramatically in design and materials used in their fabrication. Different sports may require different design features for optimal performance and comfort. The sole of a good athletic shoe is stiff at the heel and at the shank but very flexible at the fore foot, where it should bend easily

at the ball. The outer sole usually is made of highly durable rubber compounds that provide a good grip on the ground, whereas the inner sole is designed to closely fit the contours of the foot. Between the outer and inner soles, fluid, gel or cavitated materials are placed for cushioning and shock dampening. The outer sole is often designed to flare out laterally at the heel and towards the mid foot to improve the mediolateral stability at the ankle and to ensure the foot is flat as it strikes the ground in the normal, slightly supinated position. Rising up from the rear sole to a height of approximately 0.5 in. (1.2 cm) is a heel cup, which further increases mediolateral control and provides hind foot stability. The rigid and non-compressible heel counter provides added ankle and foot stability, but for athletes with a tendency for recurrent ankle sprains, there is the option of using high-top shoes. The upper is reinforced in the mid foot area for maximum stability and to resist excessive side-to-side motion. Such reinforcement is obtained by adding stiffening bands, stabilizing lacing systems, or motion control straps.

Due to their natural increase in coefficient of friction, rubber soles have more traction than leather shoes when walking on carpeted or dry surfaces. Sometimes it is desirable to reduce friction, and application of an external leather toe slider covering the front 1/3 of the sole can be of great benefit to facilitate limb advancement when limb clearance is impaired.

### Fitting

The first requirement of a shoe is that it fits and does not cause pain, skin problems, or deformities. Ideally both feet should be measured in length and width, and the shoes tried on both feet in case of size discrepancy, in which case the shoe size should be chosen to comfortably fit the larger foot while some filling material may be used in the smaller one. If more than a one size difference exist, using split size shoes is encouraged (14,15). Footwear preferably should be purchased at the end of the day, when the feet often are slightly swollen. When shoes are fitted, each shoe should be judged individually in a fully weight-bearing position. The shoe should fit snugly enough not to fall off but be loose enough to adapt to the size and shape of the foot,

which changes with climate, ambient temperature, time of day, body position, and standing weight bearing. Because the foot changes shape with weight bearing and some pathological conditions, shoes initially should be carefully tested for fit, both in length and width, not only by standing but by walking for several steps and stopping fast. In length, the shoes should extend at least a half-inch (1.2 cm) beyond the longest toe, usually the hallux or the second toe. The heel-to-ball distance of the foot and the shoe should be equal. Thus, the first metatarsal joint should be located at the inner curve of the shoe, and on toe dorsiflexion, the shoe should bend easily at the toe break that should run directly across the ball of the foot. The widest part of the shoe should coincide with the broadest part of the foot, leaving enough free space medial and lateral to the heads of the first and fifth metatarsal bones, respectively. The shoe widths measured at the ball are available in different sizes, ranging from A (narrow) to E (wide). Each size represents a 0.25-in. (0.6 cm) increase in width.

The transverse arch of the foot should function normally, weight should be evenly distributed, and no sliding of the fore foot within the shoe should occur. There should be no gap between medial and lateral quarters and the heel counter should close around the heel bone without bulges, allowing only a small amount of pistoning. The height of the quarters should be sufficient to hold the shoe securely on the foot. Some pistoning usually is unavoidable in a modified shoe with a rigid sole and heel counter. The height of the vamp should be adequate to prevent pressure or irritation over the toes and the instep. If the material is soft and pliable it should be possible to fold some material from the top of the toe box to confirm appropriate space for the toes. Shoes are not usually fabricated in different depths, although extra-depth shoes and shoes with removable insoles are available to accommodate foot abnormalities and shoe inserts. The real proof of fit, however, is if the shoe is comfortable after hours of continuous wear or walking.

If there is a pathological condition with loss of sensation in the feet, new shoes should be worn using a gradually increasing schedule starting at 2 hours/day only, after which shoes and socks should be removed and the feet carefully inspected. Before donning, each shoe should be carefully inspected visually or with the hand for irregularities or foreign objects on the inside, which could injure the foot.

### Shoe Modifications

Stock shoes may require minor or major modifications by various methods to support the abnormal foot during weight bearing, to reduce pressure on painful areas, and to limit motion or accommodate deformed, weak, unstable, or painful joints. For these purposes, the clinician may select a special type of shoe, order certain alterations in the construction of the shoe, or apply corrections directly to the foot. For this approach to be effective, the clinician needs to make an accurate diagnosis of the problem, have a clear understanding of why corrections are needed, and write a specific prescription that is best accompanied by a simple drawing to clarify the request (Fig. 76-5B).

Although certain simple external modifications may be applied easily to many types of commercial shoes, welt shoes are more suitable to work with, especially for major internal modifications, because the process of removing and reattaching the sole to the upper does usually not alter the structure of the shoe.

### Wedges and Flares

A flare is an extension attached, either medially or laterally, to the sole of the shoe intended to provide mediolateral ankle stability. The flare can be added to the heel only, or it can extend the entire length of the shoe. A flare is not intended to correct a deformity but rather only to control motion. Widening the base of support with a flare (usually lateral sole flare) may provide a more stable platform for the foot. Indications for a flare include posttraumatic subtalar instability or in patients with hind foot contractures and tone disorders that increase the tendency to roll the ankle (16).

A wedge is used to help accommodate a rigid deformity or correct flexible deformities of the hind foot. A shoe with a lateral wedge has more material under the lateral border of the foot than the medial border.

Flares and wedges may be combined in severe cases but care should be taken to avoid medial flares that exceed  $\frac{1}{2}$  in. (1.2 cm) as the patient may trip with his other foot. For lateral flairs in excess of  $\frac{1}{2}$  in. (1.2 cm) a buttress should be included for better control (Fig. 76-6).

### Lifts or Elevations

Elevations of the shoe can be used to address a variety of clinical problems. Most commonly, they are used to compensate for an acquired or congenital limb-length discrepancy or a limb-length discrepancy created by a contralateral shoe modification. When added to the contralateral shoe of a patient with a

**FIGURE 76-6.** Shoe with medial buttress.

neurological problem who has impairment in limb clearance, it can facilitate the swing phase of the affected limb.

Elevations are applied either under the heel only or under the whole foot. They can be applied internally or added to the outer sole of the shoe. A heel-only elevation is appropriate for accommodating a fixed equinus position or reducing the strain on the Achilles tendon. A buildup less than ½ in. (1.2 cm) can be easily added inside the shoe. Greater corrections will need to be distributed between the inside and outside of the shoe to avoid pushing the foot out of the shoe.

Increasing the width of the base of the shoe as the heel height increases should be considered in order to reduce the possibility of mediolateral instability. A heel-only buildup greater than 1 in. (2.5 cm) is not recommended unless accompanied by a high top shoe or an AFO to reduce the likelihood of ankle instability. A buildup that extends from heel to ball (shoe lift) is the more practical and biomechanical appropriate intervention to compensate for a limb-length discrepancy or when attempting to decrease a swing phase foot drag (17). Creating a small rocker may be necessary if the lift stiffens the sole excessively. Buildups can be added to most shoes with little difficulty.

### Rigid Shanks

An extended rigid shank is traditionally a strip of spring steel or carbon graphite of varying rigidities that is placed between the layers of the outer sole or in some cases inside the shoe, extending from the heel to the toe brake of the shoe. An extended rigid shank, as its name indicates, extends to the tip of the shoe to make it rigid, reducing bending stresses in the mid foot and fore foot and it must be used in conjunction with a rocker sole. Some of the clinical indications for this shoe modification include metatarsalgia, symptomatic hallux rigidus, and in some arthropathies or Charcot-related joint deformities or pathologies.

### Rocker Soles

The rocker sole is one of the most commonly prescribed shoe modifications (11,18). As implied by the name, the basic function of a rocker sole is to rock the foot from heel strike to toe-off without metatarsal bending. Rocker soles can effectively be used to reduce pressure under the metatarsal heads and can assist gait by easing and increasing forward propulsion in mid to terminal stance. It can reduce enough motion at the first metatarsophalangeal joint, mitigating the pain associated with hallux rigidus. It can be used to replace some of the motion lost due to the use of an extended steel shank. This type of rocker is a common feature of athletic shoes. If the rocker sole is expected to offload an area of plantar pressure, then the apex of the rocker must be proximal to the pressure area.

The actual shape and height of the rocker sole depends on the specific problem to be treated and the expected biomechanical effect of the rocker sole.

A heel-to-toe rocker sole, typically, is thicker than a mid rocker sole and has a more severe rocker angle at both the heel and the toe. It is designed to significantly reduce pressure

under the first to fourth metatarsals and to aid in propulsion at toe-off. It also decreases heel-strike forces on the calcaneus and talus, and reduces the ankle motion. This type of modification is not very effective in reducing pressure under the fifth metatarsal head (18,19). Care should be taken to assure that the rocker does not produce mid-stance instability and to encourage the wearer to walk with shorter steps to enhance the efficacy of the modification.

### Cushion Heel

Another useful shoe modification is the cushion heel, which consists of a wedge of shock-absorbing foam that is sandwiched between the heel and the sole of a shoe. The purpose of a cushion heel is to increase shock absorption and reduce the knee flexion forces occurring at heel strike resulting in a stable stance phase. A cushion heel may be indicated for patients after ankle fusion or following a calcaneal fracture. It can also be of help in patients with quadriceps weakness or patients with other forms of early stance phase knee instability.

### Foot Orthoses

In the hands of an experienced clinician, custom orthotics are an effective tool in the management of most of the abnormal biomechanics of the foot. Orthotics are designed, in principle, to be corrective or accommodative devices (9).

Corrective devices are meant to improve the position of the foot by changing the alignment of skeletal structures. Rigid materials such as thermoplastics, acrylic laminates, and carbon graphite composites are frequently used for this. Cork and polyethylene are example of materials used for semi-rigid orthotic devices that are corrective. Accommodative devices made of soft open or closed cell foams alone or in combination with semi-rigid materials are meant to provide cushioning and support to an already deformed foot structure. They prevent further deformity while ultimately improving function and controlling the direction and/or alignment of the joint movement.

Appropriate posting, longitudinal or transverse arch buildups, heel lifts, pressure relief areas, or other special modifications and the use of various materials in the same orthotic device can be integrated in the design and combined at the time of fabrication. There are several factors to consider when selecting materials used in custom orthotic fabrication; these include the type of activity, the length of time to be used, the amount of forces to be applied across the orthosis, and the amount of axial loading. Also the amount of cushioning that is desirable without introducing mediolateral ankle instability should be considered.

One example of this careful application is the use of thermoplastic elastomer (TPE) for the longitudinal arch, Pelite as a molded substrate and Poron for shock absorption in the same device (Fig. 76-7). Custom foot orthoses (FOs) are superior to prefabricated ones because they can be designed to provide corrective forces to the affected joint(s) with more optimal control. In addition, they can be configured to match precisely the patient's anatomy (of particular importance in the presence

**FIGURE 76-7.** Hybrid material FO.

of impaired sensation) and activity requirements, and they can be manufactured from a variety of materials singly or in combination.

When prescribing a FO, knowledge of the disease process in question, functional anatomy, biomechanics, materials, and finally, recognition of the anticipated functional outcomes are essential for proper prescription. Consideration should be given to the fact that external loads act as dynamic forces that may require different orthotic prescription and materials for different activities.

During the gait cycle, the foot is a dynamically changing lower limb segment, whereas the FO is a relatively static device. Careful follow-up and adjustments, as needed, are essential for long-term success with this treatment modality. Corrective FOs made of rigid materials can be extremely difficult to fit and require meticulous attention to detail (20). Progressive wearing periods of several weeks with close monitoring of the skin integrity is encouraged.

Few hypotheses regarding the use of FOs have been investigated in controlled studies; hence, much of the design variance encountered is founded on clinical experience and judgment.

FOs are the foundation for lower limb orthotic management. Not only are they suitable for treating many of the common problems encountered in daily practice, but they serve as a basic component in each and every more proximal orthosis design (e.g., AFO, KAFO or hip-knee-ankle-foot orthosis [HKAFO]).

### Ankle-Foot Orthoses

AFOs, because of their mechanical lever arm, can more effectively control the ankle complex and when appropriately designed, can influence the knee joint as well.

The clinician must choose from among metal/leather, plastic, carbon graphite, or a hybrid design assembly incorporating some or all the mentioned materials for an AFO. In general, plastic or hybrid systems predominate in North America and Europe because of the greater degree of client acceptance and control they offer (1). The choice of materials in the fabrication

of orthotics is expanding rapidly and a detailed review of them is beyond the scope of this section. It is very unfortunate that insurance restrictions, in general, prevent open access to some of the recently introduced orthotic technology such as the use of composite or graphite and new advanced design devices. The older-style metal and leather orthoses usually are reserved for selected applications, such as when minimal contact with the soft tissues is desirable due to fluctuating edema, wounds or for heat-sensitive individuals who cannot tolerate the more intimately fitting plastic contours or when fitting large or heavy individuals (2). One of the most significant factors in material selection is cosmetic appearance, which strongly affects device acceptance.

A thermoplastic or laminated supracondylar AFO, also known as a patellar tendon bearing floor reaction orthosis, is indicated for patients who lack knee and ankle muscle power but have normal hip extension strength, full knee extension range of motion, and no significant flexor spasticity (7). A molded footplate and a solid non-articulated ankle design immobilize the foot and ankle in slight equinus, which produces a knee extension force during stance phase. Potential genu recurvatum is controlled by the ligamentous structures of the knee joint or a supracondylar anterior shell and a counteracting posteriorly placed popliteal shell. Blocking plantarflexion of the foot can limit recurvatum as well.

Successful use of AFOs based on electrical stimulation of weak or paralyzed muscles has been recently reported (21). In the United States, several commercial versions of such orthoses that incorporate neuromuscular electrical stimulation (NMES) have become available for clinical applications (22). As with any other therapeutic intervention, to achieve their intended use, these devices require appropriate patient selection, understanding of the disease process, and gait biomechanics.

Equinovarus deformity is the most common pathologic lower limb posture observed in the population after central nervous system injuries. This abnormal posture results in an unstable base of support during stance phase. The contact with the ground occurs with the fore foot first, and weight is borne primarily on the lateral border of the foot; this position is maintained during the stance phase. Heel contact may be limited or missing. Limitation in ankle dorsiflexion prevents forward progression of the tibia over the stationary foot in stance phase, causing knee hyperextension and interference with terminal stance and preswing where lack of a propulsive phase is evident (7). During the swing phase, there is a sustained plantar-flexed and inverted posture of the foot, possibly resulting in a limb clearance problem. The lack of adequate base of support results in instability of the whole body. For this reason, the correction of the abnormal ankle-foot posture by orthotic means is essential. The use of an AFO to control the abnormal posture of the ankle during stance and swing phases should be attempted. An ankle inversion strap or pad should be used to assist in controlling the ankle inversion attitude. The orthosis should be attached preferentially to an orthopedic shoe and the orthotic ankle should include a plantar flexion stop to control ankle plantar flexion during swing and stance

**FIGURE 76-8.** Conventional knee-ankle-foot orthosis with variations of knee locks. (From American Academy of Orthopedic Surgeons. *Atlas of Orthotics*. St. Louis: CV Mosby; 1975.)

phases (4). If ankle clonus is triggered during the stance phase, a dorsiflexion stop will need to be used as well to prevent the stretch response triggering this phenomenon. The stop should be set just before the clonus appears. A molded foot plate with a padded long plastic foot-plate, in combination with a toe strap and an extra-depth shoe with high toe box, can be used as an option to accommodate abnormal flexed toe posture (16).

### Knee-Ankle-Foot Orthoses

Below the knee, the components of the standard KAFOs are the same as those of metal or plastic AFOs, except that the uprights extend to the knee joint, where they join the thigh uprights (Fig. 76-8). A free flexing knee joint is indicated when mediolateral instability or genu recurvatum may be present but knee extension strength is adequate for weight bearing.

If knee extensors are weak, and knee buckling into flexion occurs, a posterior offset knee joint may be indicated. In the absence of knee flexion spasticity or contracture, an offset knee joint provides a mechanical stable knee during stance but allows knee flexion during the swing phase. This type of joint can provide stance phase knee stability if weight bearing is applied to the limb by placing the orthotic knee joint axis behind the anatomical knee joint. This results in the anterior placement of the line of gravity in relation to the knee. Frequently, this will need to be combined with an ankle joint that is limited in dorsiflexion. It is important to note that this is not a fail proof system since knee instability may occur if the floor is uneven, the knee is not fully extended or loaded or the ankle is allowed to dorsiflex more than 10 degrees (2). In such case presentations, a knee lock may be a better choice. The drop-ring lock is most commonly used, it is placed on the proximal section

of the upright bar and drops over the joint when it is fully extended. A spring-loaded pull rod may be added to the ring to facilitate locking and unlocking, especially when the patient is unable to flex at the hip to reach the knee or lacks hand or finger strength and dexterity. A cam lock knee with a spring-loaded cam that fits into a groove in full extension is easier to release but still gives good stability and may be used in patients with flexor spasticity. A bail lock (i.e., Swiss lock) is a lever bow that snaps into locked position on full extension and unlocks automatically when pressed upward. In the presence of a knee flexion contracture, an adjustable knee joint that makes use of either a fan or dial lock may be appropriate. Even when mechanically locked, the anatomical knee with weak extensors would bend slightly on weight bearing if not stabilized by straps above and below the patella or by a patellar pad or strap, a soft leather pad covering the knee cap and fastened with four adjustable buckles to the uprights works well. The thigh uprights are connected by a rigid, padded, upper thigh band with an anterior soft closure. This band should be 1.5 in. (3.7 cm) below the ischium, unless ischial weight bearing is prescribed. Usually, a second, rigid lower thigh band may also be used with soft anterior straps.

The Scott-Craig orthosis eliminates the lower thigh and calf bands and the hip joint typical of a HKAF0 used in spinal cord injuries, which facilitates donning and doffing and reduces its weight (Fig. 76-9) (23). It consists of two uprights with four rigid connections: posterior rigid upper thigh band, bail-type knee lock, rigid anterior upper tibial band with soft posterior strap, and at the lower end, a stirrup with a rigid sole plate built into the shoe extending to the metatarsal heads. It is connected to the uprights by double-stop ankle joints that are

**FIGURE 76-9.** The Scott-Craig knee-ankle-foot orthosis.

adjusted to place the orthosis in 5 degrees of dorsiflexion for optimum balance (1). The shoe sole is perfectly flat from the heel to the metatarsal bar, where it becomes slightly rounded to the toe. Properly adjusted, the orthosis should stand balanced on its own. It is a stable orthosis that biomechanically functions as the standard KAFO but with fewer encumbrances from straps and relays heavily on the subject's anatomical structures such as the ligament of Bigelow.

Because the anatomic knee joint has a changing axis of rotation, polycentric designed knee joints have the ability to maintain a better alignment during knee movement than single axis knee joints and should be prescribed if the knee is to be allowed to flex in the swing phase.

### Plastic Knee-Ankle-Foot Orthoses

Plastic molded or laminated KAFOs may incorporate standard ankle and knee components, but the uprights and bands are made of lightweight laminates or thermoplastics that closely fit the limb (Fig. 76-10). The thigh piece consists of a posterior quadrilateral-shaped shell with or without an ischial weight-bearing or gluteal seat or a narrow mediolateral shaped thigh section if it is to be used bilaterally for improved comfort. The thigh section is closed anteriorly by a plastic band and a Velcro strap or a pair of padded straps. A suprapatellar or pretibial shell provides knee extension force, which eliminates the need for patellar strap and supplies mediolateral knee stability. At the lower end, the uprights are connected to a molded plastic footplate to be worn inside a shoe.

Lightweight modular KAFOs have been designed for quick and easy assembly and provided for children with Duchenne muscular dystrophy in order to extend their walking ability (24). Such a KAFO consists of a plastic thigh piece and an AFO, both available in several prefabricated sizes. The two components are joined at the knee by a metal joint system with an automatic ring or bail locks.

### Knee Orthoses

Knee orthoses (KOs) are prescribed to control genu recurvatum and to provide mediolateral stability. With improvements in design and application, KOs have gained recognition by many as a treatment and prevention modality. As such they may be used during sports and other physical activities to functionally

**FIGURE 76-10.** Plastic-laminated KAFOs viewed from side (A) and front (B).

**FIGURE 76-11.** The Swedish knee cage is an example of a KO.

support the unstable knee or during the rehabilitation phase following knee injury or surgery. However, there are many different categories of KOs leading to the confusion of many prescribers. The use of KOs for the prevention of knee injury in athletes is controversial (6,25).

The multitude of KO designs is, in part, propelled by the growing field of sports medicine and the desire to reduce the prevalence of knee injuries. Most KOs consist of two uprights with polycentric free or adjustable range knee joints, and thigh and calf cuffs. The Swedish knee cage (Fig. 76-11) has no knee joint and prevents recurvatum but permits flexion. The three-way knee stabilizer orthosis looks similar and gives good control of structural knee instability in the lateral, medial, and posterior directions and is indicated for osteoarthritis, flexible genu valgum, and genu varus, and for recurvatum of moderate severity. The standard KOs have short lever arms and may not be effective when strong forces are required for control. Most KOs tend to slip or migrate down the leg during movement, resulting in discomfort from pressure or lack of joint alignment. Following a recent publication by Chew and colleagues, KOs can be broadly classified as unloaders, prophylactic and patellofemoral orthoses (6). No long-term study is available to support the benefit of the use of the unloader brace in osteoarthritis but its effectiveness in short-term use has been documented by Pollo in 2002 (6,26).

Numerous KO designs with longer lever arms and, often, rotational control components have been commercially

fabricated and prescribed for high-level physical activities and athletics.

### Hip-Knee-Ankle-Foot Orthoses

HKAFOs consist of the same components as described for the standard AFOs and KAFOs, with the addition of an attached lockable hip joint and a pelvic band to control movements at the anatomic hip joint. The movement in the mediolateral plane is controlled with the single axis design while the sagittal motion may be controlled usually with a ring drop lock. The pelvic band, which may be unilateral or bilateral, encompasses the pelvis between the iliac crest and greater trochanter laterally, curves down over the buttocks, and then passes up again over the sacrum. The indications for prescribing a pelvic band have been controversial because several studies indicate that it increases the lumbar excursion and displacement of the center of gravity during ambulation, and thus energy cost may be greater. For most persons with paraplegia, pelvic bands probably are not necessary if they are candidates for Scott-Craig orthosis, although they may improve the standing balance, especially if flexor spasticity is severe.

The Louisiana State University reciprocating gait orthosis (Fig. 76-12) consists of bilateral KAFOs with posterior offset knee joints, knee locks, posterior plastic ankle-foot and thigh pieces, a custom-molded pelvic girdle, and special thrust-bearing hip joints, coupled together with a cam and a thoracic extension with Velcro straps (27,28). The cam mechanism provides hip stability by preventing simultaneous bilateral

**FIGURE 76-12.** Louisiana State University reciprocating gait orthosis.

hip flexion, yet allows free hip flexion coupled with reciprocal extension of the contralateral hip when weight shift during a step is attempted. Using two crutches, persons with paraplegia are able to ambulate with a four-point reciprocal gait pattern. This orthosis also has been tested and used in conjunction with a functional electric stimulation system to facilitate ambulation by persons with paraplegia.

Newer orthotic systems that allow the knee joint to flex in the swing phase of walking and provide stability in the stance phase (stance phase stabilized orthosis) are slowly becoming more common. The system may use mechanical or electronic systems to achieve knee locking in stance and unlocking in swing phase. Increased weight, cost, and maintenance are the main disadvantages. While normalization of gait pattern with likely reduction of energy consumption in the well-trained subject are the principal advantages (29).

Powered HKAFOs that support independent hip and knee movements through computer-controlled motors in the swing phase and joint stability in the stance phase are undergoing clinical trials (30). This device affords independent sit to stand transfers, a reciprocal gait pattern on level surfaces, ramps, and curbs (Fig. 76-13).

### Fracture Orthoses

Orthoses of different designs have been used in the management of fractures (31). By definition, a plaster-of-Paris cast applied to a fractured limb is an orthosis that provides rigid immobilization while healing occurs. The term “fracture

orthosis,” however, refers to a concept of management based on the hypothesis, supported by considerable clinical evidence, that mobility of adjacent joints does not impede healing of fractures in most cases, that functional activity stimulates osteogenesis, and that rigid immobilization of fractures is not a prerequisite for healing. Even when this management concept is applied, all fractures initially are immobilized either by traction or in conventional casts while the acute pain and swelling associated with the injury subsides and early healing takes place. In general, such immobilization should be maintained for at least 3 weeks, but no more than 6 weeks, before the fracture orthosis is applied. The initial immobilization is done to minimize leg shortening. Problems associated with fracture orthoses are increased angulation of the bone and refracturing, both of which are rare. Fracture orthoses have been used most often to treat fractures of the shafts of the tibia and femur when internal fixation is unnecessary, contraindicated, or refused by the patient and when healing is significantly delayed. Fracture orthoses are contraindicated when satisfactory alignment of the fracture cannot be obtained or maintained.

Initial efforts to use orthotic devices for lower extremity fractures were inspired by lower extremity prostheses. Three basic components are required for fabrication of a fracture orthosis: a cylindrical containment, footplate, and joint mechanisms. The cylindrical component closely fits the fractured limb to provide a hydraulic mechanism that will promote stability for the bony structures and resist shortening. The vertical load from weight bearing is offset by lateral and oblique forces from an essentially incompressible fluid chamber that is created by the encasing cylindrical orthotic component. Most proximally on the orthosis, a weight-bearing surface may be provided, such as a patellar tendon-bearing socket or ischial or gluteal seat, to reduce the vertically directed forces on the fracture site. This mechanism is far less important in the distribution of weight-bearing pressures than the hydraulic mechanism mentioned. The cylindrical components usually are made of plaster-of-Paris cast or low-temperature thermoplastics (Orthoplast). The second major component of a fracture orthosis is a footplate, which is to be worn inside a shoe. The footplate usually is prefabricated and made of plastic, although custom-made footplates occasionally are made. The footplate usually is attached to the cylindrical component by simple plastic hinges rather than metallic joints. Similar joint mechanisms may be used for the knee, connecting the tibial and femoral sections.

Appropriately designed and fitted, fracture orthoses allow functional ambulation with progressively increasing weight bearing. Absence of pain, good callus formation, and lack of gross motion at the fracture site indicate that the fracture is well stabilized. Fractures of the distal tibia can be treated with a below-knee patellar tendon weight-bearing orthosis (Fig. 76-14). Fractures of the proximal tibia, especially those involving the knee articular surface, generally require a thigh piece that is connected to the leg portion with a polycentric knee joint (32). Fractures of the mid- or distal femoral shaft are managed more successfully with fracture orthoses than are

**FIGURE 76-13.** ReWalk robotic powered orthosis.

**FIGURE 76-14.** Orthosis for fracture of the tibia. (From American Academy of Orthopedic Surgeons. *Atlas of Orthotics*. St. Louis: CV Mosby; 1975.)

fractures of the proximal femoral shaft because of the latter's strong tendency to produce varus angulation and malalignment. The femoral component of the orthosis resembles that of the quadrilateral above-knee prosthesis with an ischial seat and a three-point fixation contour that resists varus angulation (Fig. 76-15). The femoral component is connected to the tibial section by freely moving plastic joints or metal hinges that allow sagittal motion. The tibial section, in turn, is attached to the footplate by joints, as seen in the tibial fracture orthosis (see Fig. 76-14).

Functionally, all orthotic devices aim to control motion, correct a deformity, and compensation for muscle weakness. Orthoses should be prescribed based on the desired biomechanical function (2). A functional problem-oriented based prescription, such as "orthosis to compensate for ankle dorsiflexion weakness," ensures that the communication with the orthotist is accurate, producing the best solution for a particular patient (4). Further specifying the desired materials or specific joint type, function or motion limitations should be pursued only when clear understanding of gait biomechanics and knowledge of available orthotic components exist. If this knowledge is not readily available, the prescription should be discussed with the orthotist. Physicians should aim at expanding their knowledge of such information to issue the most appropriate prescription.

A complete orthotic prescription should consider the type of footwear to be used, include the joints it encompasses, suggests the desired biomechanical alignment and materials of fabrication for the orthosis. In the very active adult, accommodative orthoses may need to be replaced often to adjust for material deterioration while in the child

**FIGURE 76-15.** Front (A), side (B), and rear (C) views of an orthosis for fracture of the distal femur. (From American Academy of Orthopedic Surgeons. *Atlas of Orthotics*. St. Louis: CV Mosby, 1975.)

this should be done to accommodate for growth. The cost of these custom devices, depending on regional variations and availability, has a wide spectrum. For the less complex accommodative devices, price is not significantly different than that for prefabricated ones.

### Clinical Orthotic Alignment

Informal visual analysis of gait is routinely used by clinicians to improve the dynamic alignment of an orthosis. This type of analysis does not provide quantitative information and has many limitations due to the speed and complexity of human locomotion (22). Gait deviations and compensations, present in the walking pattern of individuals who use orthotic devices, further complicate the alignment methodology. Traditionally, a trial and error system is used to attain the best dynamic alignment of a brace (33).

Commonly, clinical observation and patient feedback are the primary sources of information on orthotic alignment. Usually, joint position and/or range of motion are continually adjusted until both the clinician and the patient are satisfied. For this approach to work, several factors need to be present: the clinician needs to have a keen biomechanical sense, the patient should be able to provide “good” feedback and there should be only a unidirectional set of joints to adjust. Unfortunately, these conditions are not always present nor are they the only factors that will affect the alignment process. Even under ideal circumstances, orthotic alignment cannot be completely and accurately evaluated until the patient has had a chance to walk in and accommodate to the device over time, and until a stabilization of the compensatory muscle strategies and symptoms has occurred.

### Gait Analysis

Gait analysis affords the clinical team the opportunity to infuse the much needed objectivity into the process of orthotic alignment assessment. Experienced clinicians may back their biomechanical orthotic prescription process with the use of special quantitative and semi-quantitative assessment methods including (in order of frequency of use): video recording (slow motion and instant replay) and instrumented gait analysis (Kinematics [temporal and spatial measures and motion analysis], kinetics [force analysis], dynamic electromyography [analysis of muscle activity], and energetics [metabolic]) (22,33,34).

In some laboratories, force platforms when combined with special hardware, permit real-time visualization of a force vector (22,33). This technology provides an excellent visual estimate of the magnitude and polarity of a joint stance-phase movement. Based on its semi-quantitative nature, simplicity and no need for instrumentation of the subject, this information is of significant importance when attempting to optimize biomechanical orthotic alignment (Fig. 76-16).

### Clinical Scenarios

Application of an orthosis to address the abnormal base of support during walking. The lack of adequate base of support results in instability of the whole body. Equinus or

**FIGURE 76-16.** Force line over brace.

equinovarus deformity is the most common pathologic lower limb posture seen in neurological rehabilitation. This abnormal posture results in an unstable base of support during the stance phase. The contact with the ground occurs usually with the fore foot first, and weight is borne primarily on the lateral border of the foot, this position may be maintained during the stance phase if spasticity is present. Limitation in dorsiflexion prevents forward progression of the tibia over the stationary foot, causing knee hyperextension and interference with terminal stance and preswing where lack of propulsive phase is noted. During the swing phase there is a sustained plantar-flexed and inverted posture of the foot, potentially resulting in a limb clearance problem. The use of an AFO to control the abnormal posture of the ankle during the stance and swing phases can be considered. If an inversion deformity is present, an ankle inversion strap or pad is used to control this problem. The orthosis should be attached to an orthopedic shoe and include a plantar flexion stop to prevent excessive ankle plantar flexion. If ankle clonus is triggered during the stance phase, a dorsiflexion stop can be used as well to prevent the stretch response. When cognition and sensation are not impaired, the use of a molded plastic ankle-foot orthosis (MAFO) with inversion control wing buildup is preferred. A long plastic foot-plate with soft padding, in combination with a toe strap and an extra-depth shoe with high toe box, can be used to accommodate abnormal toe posture (Fig. 76-17).

### Application of an Orthosis to Limb Instability During Walking

Knee flexion during early stance phase results in limb instability. In central nervous system problems, patients exhibit this

**FIGURE 76-17.** Curled toes in brace with shoe toe box removed.

problem more commonly in the early phase of neurological recovery, with flaccidity and weakness affecting the limb. The same functional problem may be evident in peripheral nerve injuries. The patient is unable to control the knee flexion movement during the early stance phase and is unable to walk without upper limb assistive devices. If external means of knee control are provided through a KAFO, KO, or AFO during early stance, the patient most likely will be able to maintain limb stability and to ambulate. A KAFO with off-set knee joints, a floor reaction AFO set in a few degrees of plantar flexion, or a shoe with a cushioned heel can improve knee stability. It is important that a knee extensor strengthening exercise program be implemented, as knee weakness is promoted by the muscle disuse that the orthotic interventions may cause (7).

## GAIT AIDS

Canes, crutches, and walkers are often prescribed to assist walking in persons with joint, muscle, and sensory functional losses (Fig. 76-18).

Canes serve many functions. They are an important component in the management of persons with balance deficits. Cane use can increase the anteroposterior and mediolateral base of support. They provide an important safety-related function, providing information related to the position of the limb in space, and assist the individuals with vision-impairment such that they can use the device to scan the environment. Increased joint force reaction has been associated with subjective discomfort at a joint, this is likely further compounded by weakness. A cane, when properly positioned, can decrease the amount of muscle force necessary to stabilize a joint. This in turn leads to attenuation of joint reaction forces and decreased pain symptoms. Muscle weakness may also be offset with cane

**FIGURE 76-18.** Gait aids.

use, where gait deficits such as excessive knee or hip flexion may be overcome. Pathological conditions affecting the upper limbs may interfere with the use of canes or crutches, and may warrant the prescription of specially designed gait aids.

In the patient with hemiplegia, the cane should be held in the less-affected hand, and the patient instructed to advance the cane and weaker leg simultaneously to attain a three-point gait pattern. When ascending stairs the same patient advances the less-affected (stronger) leg first. The reverse pattern is recommended when descending stairs, with the weaker limb plus cane leading.

When treating hip joint pain or hip muscle weakness, the cane should be held on the opposite side whilst for the knee it may be held on the same side.

Canes consist of a handle, shaft, and base (see Fig. 76-18). Of course, improper fit severely diminishes the effectiveness of the device. Canes are most commonly made of hard woods or aluminum. Designs vary, but all should be fitted with a deeply grooved 2- to 5-cm rubber tip for safety. Several types of tips are available to be attached to the cane shaft. In general, the total height should equal the length from the base of the heel to the upper border of the greater trochanter (35). A single-point cane weighs less, which is important for individuals with decreased functional reserve or upper limb weakness. It is less intrusive, and may be easier to negotiate in cramped spaces. Where stability is compromised, a wide-based cane may provide a greater base of support. These designs consist of three or four short legs attached to a single upright. Three- or four-prong canes have the added advantage of remaining standing when they are released. These canes are often heavy and awkward to use, and temporary use is thus preferred. Cosmesis may also be an important consideration with wide-based cane use.

The most common handle is the “C”-type. It is inexpensive, but this type of handle may be uncomfortable to use

and difficult to grasp for individuals with hand pathology. Additionally, the line of support differs from the cane's line of action, which produces a bending moment that must be overcome with muscular effort. An alternative approach is a "functional" or ortho-eze handle. A functional handle better conforms to the natural angle of the hand and is centered over the cane shaft (reducing the bending moment). This type of cane is perceived as more comfortable and provides better support while reducing the strain on the wrist and fingers. However, functional handles increase the cost of the device.

The rationale for crutch prescription is similar to canes. The clinical deficits, however, are usually more pronounced. Good upper extremity strength, joint integrity, and ROM are essential to maximize benefit with crutch use. Shoulder flexors and depressors, elbow and wrist extensors, and finger flexors must have normal or good strength. Most commonly, crutches are prescribed to decrease loading, with muscle weakness or joint pain. Where "push-off" is limited in locomotion, crutch use may aid in forward propulsion. Crutches provide sensory feedback and increase the base of support. Yet they are less commonly prescribed for balance deficits compared to canes.

Crutch types include axillary, Lofstrand, Canadian elbow extensor (i.e., triceps crutch), and forearm support (platform crutch). Axillary crutches are the most common. They are typically made of hardwood or aluminum, with two upright shafts and a series of connecting links. Connections include a padded upper support, middle hand piece, and lower extension. The extension piece and shaft, have numerous, regularly spaced holes for height adjustment. A soft, rubber tip (similar to canes) is attached at the bottom to increase the crutch contact surface area and provide additional stability. Again, proper fit is essential. Total length and handle height are the main considerations. Axillary crutch length should approximate the distance from anterior fold of axilla to: (a) bottom of heel (plus 3 to 5 cm) or (b) a point 6 in. in front of the anterolateral border of the foot.

Drawbacks include increased assistive device mass and restriction of hand use. Some patients may have trouble coordinating gait pattern with crutches. Additionally, patients who lean on the axillary crutches may experience neurological compression injury in the axillary area (i.e., crutch palsy).

The Lofstrand crutch consists of a molded hand piece, a molded forearm piece bent posteriorly just above the hand piece, and a single, length-adjustable aluminum tubular shaft. The forearm piece extends 4 to 5 cm below the elbow. A forearm cuff with a narrow anterior opening is attached at this site. Lofstrand crutches are, typically, lighter in weight, and the hand piece can be released without losing the crutch. The result is that the hands are freed up to perform some activities, which is a significant advantage. Good upper extremity strength and adequate trunk balance are minimum requirements for safe use of Lofstrand crutches.

The triceps crutch extends just above the elbow, and has a single aluminum upright attached to the bilateral uprights.

This crutch is rarely prescribed, but may be of benefit in individuals with triceps weakness. Forearm support (platform) crutches may be prescribed when clinical conditions involving the hands, wrists, or forearms prevent safe or comfortable weight bearing. Examples include weakness of triceps or grasp, or arthritic conditions involving the upper extremity joints.

A walker is a frame device that is inherently stable. There are different types of walkers, the most common of which are made of aluminum, have four posts, and may have small front or rear wheels. The person pushes or lifts the walker in front of himself or herself while walking. Walkers have advantages and disadvantages, all of which should be considered when prescribing such an assistive device.

Walkers provide a wider base of support than either canes or crutches, resulting in increased stability. They may be prescribed for patients requiring maximum assistance for balance or with severe sensory deficits, ataxic conditions, and persons with substantial fear of falling. They may be useful during rehabilitation, but care should be taken to assure that the patient does not become too reliant or emotionally dependent on the stability provided by the walker.

Proper use requires bilateral grasp and arm strength. They are bulky in appearance, may be difficult to maneuver in tight quarters, and interfere with the development of reciprocal gait. The use of a walker may tax the endurance of the user's arms. To cope with fatigue, four-wheeled walkers exist and may be outfitted with a seat to make it possible to have intermediate periods of rest. This practice is not risk-free, and the walker should ideally be fitted with hand brakes.

Most walkers are too light for individuals with incoordination. When coupled with good upper extremity strength, weight may be added to this type of walker to attenuate this problem. Walkers can be instrumented with wheels to promote better gait timing without having to stop each cycle to advance the walker. Wheels help patients with incoordination or weakness of the upper extremity, where lifting crutches or walkers and placing them forward may be difficult. The rolling (wheeled) walker does not require as much strength and balance to maneuver, compared to non-wheeled walkers, as the user does not have to lift it from the floor. However, the instability introduced by the wheels, if allowed to roll uncontrolled or to swivel, may prove dangerous.

## SUMMARY

We have reviewed the basic principles of orthotic intervention, shoe modifications as they apply to the rehabilitation of patients with upper and lower motor neuron pathology. The majority of patients surviving a stroke and other brain insults achieve limited ambulation, and the use of orthoses or other assistive devices attempt to optimize their functional capabilities and encourage improved functional level and quality of life. Orthoses are devices that are applied to the external surface of the body to achieve one or more of the following; relieve pain, immobilize musculoskeletal segments, reduce axial load,

prevent or correct deformity, and improve function. Orthotics for the lower limbs is an integral part of the rehabilitative medical management of the patient population we serve.

# Spinal Orthotics

An orthosis is a mechanical device that applies forces to the body in an effort to support, limit, and stabilize moving parts, assist and improve motion, correct and align deformities, and prevent and protect susceptible areas. The location, direction, and magnitude of these forces vary with the components and design of the orthosis. The word orthotic is derived from the Greek word “orthos,” meaning straight, normal, or true. Orthotics, also called braces or splints, have been known since the ancient Egyptian era. Their use continues till today; however, changes and advances in materials and techniques of fabrication, interrelated with newer surgical procedures and medical treatments, have expanded their applications.

An orthotist is a professional who designs, makes, and, with the referring physician, helps prescribe the proper orthosis for a patient. Orthoses can be prefabricated to fit a large variety of patients or custom molded to a specific patient. Their effectiveness is directly dependent upon the proper fit and alignment of the components as well as proper use and compliance by the patient. The physician and orthotist should prepare a detailed prescription together in order to avoid delivering the wrong device. Once delivered each should be present to “check out” the device in order to ensure proper fit.

The prescription of an orthosis requires an understanding of the pathology of the disorder to be treated and must take into account the goals to be achieved. Knowledge of anatomy, biomechanics, and kinesiology, and an understanding of the indications (positive effects) and limitations (negative effects) of the orthosis are paramount when prescribing such devices.

One should not get confused by the myriad classifications and names for orthoses. Some are named for their founder, others for the location where they were developed, and still others for the parts of the body to which they are applied. The most standard way to name an orthosis is by the joints that it encompasses and the motion it controls (1). In this chapter we review the different types of spinal orthotics, indications for their use, positive and negative effects, and problems that may interfere with the ongoing rehabilitation of the patient. Braces for scoliosis and osteoporosis are not covered in this chapter (see Chapters 32 and 33, respectively).

## MECHANISM OF ACTION

Spinal orthotics are prescribed for a variety of reasons (Table 77-1). They are designed to protect the spinal column

and supporting structures (ligaments and muscles) from loads and stresses that can cause pain or progression of angular and translational deformity. The physiologic mechanisms responsible for this protection are control of motion, trunk support, and spinal alignment (2).

### Control of Motion

The control of motion depends on the flexibility of the device. Numerous studies have attempted to quantify the degree of motion restriction. The most minimal limitation in gross movement likely occurs because the device acts as a physical and kinesthetic reminder to the patient not to move in harmful ways. Braces such as soft collars or lumbar corsets are examples of these. These types of devices also serve to provide warmth and heat to the patient, which may reduce spasm and pain. More restrictive braces act to limit intersegmental spinal motion and further, inhibit flexion-extension, lateral bending, and axial rotation.

### Trunk Support

Trunk support is achieved by an increase in the intra-abdominal pressure. An increase in the thoracoabdominal pressure reduces the demand on the spinal extensor musculature and the vertical loading on the thoracolumbar spine and the intradiscal pressure.

### Spinal Alignment

Spinal alignment is achieved by the application of the three-point force system inherent in all bracing. The corrective component ideally is located midway between the opposing forces above and below it. These systems shift forces from diseased areas to more healthy segments and prevent unopposed forces from causing deformity.

At each spinal level, orthoses require different designs to achieve their desired function. The desired physiologic effect must be decided upon when prescribing an orthosis so that the least restrictive device capable of completing the job is ordered. For example, if trunk support by thoracoabdominal containment is sufficient to reduce the compressive forces on the spinal column and stress on the musculature, then joint motion stabilization should not be required (2).

Before prescribing an orthosis, one must begin with the indication and develop a goal and then decide which orthosis will achieve the desired goal. Once that goal has been achieved and the device is no longer needed, the device should be

**TABLE 77.1 Indications for Spinal Orthotics**

Stabilize the spine after fracture (with or without neurological deficit)
Limit spinal motion in cases of pain or sprain
Support posture and prevent deformity after paralysis
Postsurgical stabilization (with or without fracture)

discarded. Considerable diversity and controversy can surround the choice of an orthosis and the length of time needed for immobilization. Specific guidelines are generally lacking.

Spinal orthotics are divided into groups by the joints they encompass. Within each group, there are many different designs (Table 77-2). They may further be differentiated by the motion they restrict or allow.

It is essential to be aware of the negative effects of bracing. Weakness, atrophy, and contracture may follow restriction of motion and muscular activity. Skin irritation from poor fit, hygiene, and pin site shear and pressure, can result in ulceration, pain, and infection. Impaired ambulation and balance can result from the limitation in motion and weight of the device such as with a halo device, which in turn, may make an individual more dependent in their activities of daily living. Eating and swallowing may become compromised due to the position of the head and neck. There can be a decrease in pulmonary capacity due to the restricted chest wall motion and an increase in energy consumption. Psychological dependence on the brace can also develop. This should all be taken into account when prescribing these braces because patients with certain medical conditions (e.g., neuromuscular disease), body types, and personalities may not be able to tolerate them.

Effective spinal bracing, therefore, is a complicated procedure and needs to take into account multiple factors. It is contingent upon correct fit, patient compliance, body habitus, the ability to restrict gross and segmental vertebral motion and the ability to minimize and prevent the negative side effects. Compliance is dependent on the patient's understanding of the condition, willingness to tolerate a snug fitting appliance, and overall comfort. Discomfort may be related to strap tightness, complaints of confinement, or increased perspiration caused by the brace. With patients who can volitionally adjust the straps, the effectiveness of the brace may be compromised if they loosen the straps. Individuals with a short stout neck

**TABLE 77.2 Categories of Orthoses**

Cervical (CO)—soft or rigid head cervical (Philadelphia, Aspen, Miami, Newport)
Cervicothoracic (CTO)—Halo, SOMI, Minerva, any rigid collar with an anterior or posterior extension
Thoracolumbosacral (TLSO)—custom-molded body jacket, CASH, Jewitt
Lumbosacral (LSO)—chairback, Knight, corsets/binders
Sacroiliac (SO)—trochanteric belt, sacral belt, sacral corset

and no defined chin are harder to fit with a cervical collar. Pendulous breasts, short trunk, thoracic kyphosis, or an obese abdomen make it difficult to comfortably fit cervicothoracic or thoracolumbosacral appliances. Two braces may need to be given to the patient so that one can be washed on a regular basis in order to maintain hygiene. Skin under the brace needs to be checked and washed daily. While in the brace, an exercise program should be implemented, if possible. Once the brace is discontinued, a more aggressive strengthening and stretching program is initiated in order to prevent the negative effects of disuse. In addition, the patient or caregiver must be instructed in the donning and doffing of the orthosis, its wearing schedule, whether or not the patient needs to sleep and shower in the brace, and the length of time the orthosis is recommended. Follow-up of its continued use is required both for the physician and the patient.

## CERVICAL ORTHOSES (COs)

Cervical bracing can be categorized in several different manners. In general, these devices can be subdivided into two broad categories: cervical and cervicothoracic. Cervical devices encircle the cervical spine, whereas cervicothoracic braces extend into the thoracic spine. When adding a thoracic extension piece, the cervical orthosis (CO) provides greater motion control of the lower cervical spine. To limit extension and hyperextension of the cervical spine, an intimate fit under the occiput must be achieved.

With cervical appliances, the ability to control cervical motion varies significantly from the soft collar that provides minimal restriction to the halo that offers significant reduction in movement. Several studies have examined the effects of various orthoses on mean cervical range of motion (3–8). Many of these studies used different methods to quantify the amount of restriction (e.g., radiographic analysis, goniometric assessment, and computerized spinal motion analysis). In addition, the sample size and characteristics varied from study to study (i.e., cadaver models, healthy spines vs. injured spines). Table 77-3 outlines motion restriction (3–8). For the orthotic to restrict motion adequately, it must fit properly and be worn correctly.

## Cervical Biomechanics

The cervical spine is a highly mobile structure allowing flexion, extension, lateral flexion, and rotation; thus, motion occurs in three planes: sagittal, frontal, and transverse. The atlanto-occipital joint primarily permits flexion and extension, with minimal axial rotation and lateral flexion. Functionally, this synovial joint enables an individual to nod their head. At the atlantoaxial (C1-2) joint, the predominant motion is rotation. Having no vertebral body or disc, the atlas rotates around the odontoid axis. Cervical rotation begins first at this articulation and then proceeds caudally. Approximately, 50% of the total rotation achieved by the cervical vertebral column occurs at C1-2. Between C4 and C7, maximum flexion and extension

**TABLE 77.3** Effects of Cervical Collars on Percent Mean Motion Permitted

<sup>a</sup>Richter only studied the upper cervical spine.

occurs, with the greatest motion occurring at C5-6. During flexion the vertebral foramina open and with extension close. Lateral flexion (lateral side bending), however, occurs between C2 and C7 in the coronal plane. Given the configuration of the articulating facets, lateral flexion and rotation are coupled motions. As right rotation occurs, it initiates right lateral flexion and as left cervical rotation occurs, it initiates left lateral flexion. Sagittal motion occurring at C2-7 is uncoupled. The C2-4 region has the most side bending and rotation.

### Soft Cervical Collars

A soft cervical collar is prefabricated foam rubber with a cotton stockinette covering and Velcro closures (Fig. 77-1). These closures are worn posteriorly. Depending on the patient's dexterity and upper extremity range of motion, some can only fasten the closures anteriorly and rotate the collar around their

**FIGURE 77-1.** Soft cervical collars.

neck while others leave the Velcro closures in the front. The manufacturer's intention was to have these collars worn with the closures facing posteriorly. Collars range in size from small to extra large. To identify the correct size, circumferential neck measurements are taken. This measure corresponds with predetermined sizes. Patients tolerate this device very well. Carter and associates reported that the degree of motion restriction achieved with the soft collar was dependent on the velcro closure position (5). If the intent is to limit flexion, then the collar should be worn in the reverse position with the tabs facing anteriorly. The explanation for this is a function of the starting position of the head. Given its soft material construction, the soft collar can only provide warmth, psychological reassurance, and kinesthetic reminders to limit cervical range of motion; it cannot provide structural support. Essentially, this orthoses reminds the patient not to move. Its use may be appropriate to treat mild muscular spasms associated with arthritic changes and mild soft-tissue injuries.

Soft collars are often prescribed for the early management of whiplash injuries. The effectiveness of its therapeutic use is under scrutiny. A study evaluating whether or not a soft collar reduced the duration and intensity of the patient's pain following a whiplash (9) showed that test patients wearing a soft collar and control patients not wearing a soft collar reported persistent pain for at least 6 weeks postinjury. Hence, wearing a collar did influence the patients' pain. In a randomized prospective study (10), comparing the effect of early mobilization wearing a soft collar versus not wearing a soft collar, a significant finding was the number of days it took the group with the collar to return to work. Those who wore the collar took twice as long to return to work (mean 34 days) whereas the mobilization group without the collar returned to work sooner (mean was 17 days). In another randomized controlled study (11), examining the effect of early mobilization versus the use of a collar in patients sustaining a whiplash injury, found that those patients who participated in early mobilization rated their pain and disability less than those wearing a soft collar at 6 weeks after injury. At 6 weeks, the exercise group rated their pain less in the neck and shoulder and had fewer headaches. The early mobilization group was seen by a physical therapist for exercise instruction. In 2006, the same group of researchers published their findings using the same cohort except the patients were 6 months out and the results were the same. Patients who engaged in physical therapy with active exercises had less pain at 6 months than those treated with a soft collar (12). Considerations regarding the negative effects of brace wearing (i.e., psychological dependency, muscle atrophy, etc.) should be weighed under this condition.

### Hard Cervical Collars

These rigid prefabricated COs are used for either prehospital trauma immobilization or long-term management in patients who sustained a cervical injury. Examples of collars used for prehospital emergency stabilization are the Philadelphia, Stifneck, Ambu, and the NecLoc. These collars are either a one- or two-piece design. Each of these devices is radiolucent and also CT

and magnetic resonance imaging (MRI) compatible. With the exception of the Philadelphia collar, these extrication collars are used for short-term use. The purpose of these prehospital collars is to aid the rescuer in maintaining spinal alignment and stabilization in patients with potential or actual cervical injuries during transport. Using six fresh cadaver geriatric spines, Bednar concluded that the Stifneck and Philadelphia collars did not provide significant mechanical immobilization in the unstable cervical spine and may be ineffective in preventing displacement (13). This study questioned the effectiveness of these collars during field use. The results have to be considered carefully in light of the sample size and population studied. Nevertheless, the prehospital standard of care is to immobilize the cervical spine with a rigid collar with sandbags or foam blocks anchored to both sides of the head on a back board.

For long-term patient management, the Philadelphia, Miami J, Aspen, Newport, or Malibu orthoses have been used. The Newport orthoses was replaced by the Aspen collar. Each of these orthoses is available in pediatric and adult sizes. Typically, these devices are prescribed for mid-cervical bony or ligamentous injuries, postoperative stabilization, or post-halo removal. Some specific clinical conditions are anterior cervical fusion, anterior discectomy, and cervical strain. If spinal instability exists, these rigid devices are contraindicated. These appliances are being used as the first line of treatment instead of traditional halo devices for the conservative management of stable upper cervical fractures in adults (14–20). Examples of these fractures include: unilateral avulsion fracture of the transverse atlantal ligament (20), Jefferson fracture, (burst fracture of C1) (14,16), Hangman's fracture (traumatic spondylolisthesis of the axis-C2 on C3) (15,16,18), isolated lateral mass fracture of the atlas (19), and certain types of odontoid fractures (15–17). Studies analyzing patient outcomes in the aforementioned situations showed stable fracture healing, and no increased disability or neurologic compromise on follow-up examination (14,16,18–20). In addition, these devices are cost-effective, easily applied, and do not have the increased risks associated with the use of the halo. Frequent diagnostic imaging to detect possible instability is strongly recommended. Each of these devices is radiolucent and CT and MRI compatible.

The Philadelphia collar is a two-piece design constructed from closed cell Plastazote foam with molded chin and occipital support. Anteriorly it extends from the mandible to the sternum and posteriorly it extends from the occiput to the upper thoracic spine. The Miami J, Newport, and Aspen collars are two-piece polyethylene shells with internal padding. The Miami J collar offers greater customization; the anterior and posterior shells permit angle adjustability around the chin and occiput allowing for individual differences in bony anatomy. The Newport collar has superior and inferior adjustable supporting tabs that distribute the load along the occiput, upper thoracic spine, sternum, and upper trapezius. Each of these collars has an anterior opening to accommodate a cricothyrotomy/tracheotomy. Given the increasing prevalence of

latex sensitivity, physicians may want to consider this when prescribing COs; the Philadelphia, Miami J, Aspen, and Malibu collars are latex free.

According to Goutcher and Lochhead, some patients while wearing a hard cervical collar, Stifneck, Philadelphia, or Miami J, exhibit a significant decrease in maximal mouth opening (21). In their study evaluating the above listed collars, 51 male and female volunteers' inter-incisor distance was measured with and without a collar. In an unpredictable manner, several subjects displayed a reduced inter-incisor distance that was less than or equal to 20 mm. This reduced excursion could obstruct a physician's visualization of the glottis with a laryngoscope. For some patients, their results suggest that attempting tracheal intubation with a collar in place could be difficult. Should a patient require an emergency tracheal intubation, the authors recommend maintaining manual cervical stabilization with the removal of the anterior shell of the collar before attempting intubation.

When prescribing cervical collars with removable padding such as with the Miami J and Aspen, a second set of replacement pads should be included. The patient needs a second set to replace soiled and odorous pads, to allow moist pads to air dry after patient showering or perspiring, and when the pads show wear. Since these pads can be cleaned, it is not necessary to discard them. For specific cleaning directions, have the patient consult the manufacturer's guide. Proper cleaning prevents skin irritation. Patients with long hair should be advised to wear their hair outside the collar to prevent irritation.

When assessing fit or proper donning of the COs, look at the patient's face to determine if the chin is centered in the anterior piece. If the chin extends beyond the collar edge, it is too small. If the chin falls inside the collar it is too large. These visual markers indicate whether or not the device is sized or donned correctly. Patients should be familiar with proper donning and doffing procedures.

Furthermore, patients and caregivers should be educated regarding its effects on ambulation. Since the collar forces the patient to look straight ahead, patients should be warned that they will not be able to look down to see their feet or what is below them. As a result the patient must be alert to tripping hazards, that is toys on the floor, cracks in the sidewalk, pets, loose rugs, etc. Since geriatric patients are prone to tripping and falling, the physician should consider ordering the home care therapist to evaluate the home environment for potential environmental hazards and to formulate safety recommendations.

Barry and associates found that wearing a cervical collar affects the driving performance in healthy men and women (22). In a prospective randomized study, 23 volunteers wore a Philadelphia collar while driving and the following parameters were measured: velocity, acceleration, cervical rotation, and driver's blind spot. Their results showed that drivers were able to stop, turn, and control the vehicle but drove slower. The driver's blind spot was larger with the collar on than without it. A larger blind spot does affect merging and lane change. Overall, the researchers found that the drivers'

exhibited greater caution. Based on their design and sample size, the authors could not conclude that wearing a collar leads to an increased incidence in motor vehicle accidents. Patients should be advised about the increased blind spot associated with wearing a collar.

Pressure ulcer formation is a potential complication of rigid collar use. Fragile or insensate skin is particularly vulnerable to ulceration. Common areas susceptible to damage are the occipital protuberance, mental protuberance of the mandible (chin), clavicles, and ears. These wounds may be the result of pressure, shear, or moisture accumulation. A poorly fitting orthotic could exert an external pressure greater than the acceptable skin pressure of 25 to 32 mm Hg; when this occurs tissue ischemia ensues, resulting in an ulcer. In addition, shearing forces can arise due to facial hair and skin sliding over the collar surface, or from positional changes. For example, when a patient moves from supine to a semi-Fowler position in preparation for getting out of bed, or if the patient slides down toward the foot of the bed, shear forces can develop. Since beards increase the shear forces, it is suggested that patients shave regularly. Since constant collar wearing increases the local skin temperature, excessive perspiration in and around the area can occur. Constant moisture macerates the skin, inducing breakdown. Jirika et al. found that patients with moist skin were four times more likely to develop skin breakdown compared to those with dry skin (23). Provisions should be made to keep the skin clean, dry, and cool.

To assess for skin breakdown, remove the anterior shell to inspect the chin and clavicles, then refasten the straps before log rolling the patient onto his or her side. Remove the posterior portion and inspect the occipital protuberance and ear lobes. When removing or applying the collar or a portion of it, the physician must maintain proper neck alignment to prevent injuring the cervical spine. Prior to discharge, patients should be advised to contact their physician if they notice any redness or pressure sores.

Plasier et al. conducted a study to evaluate the craniofacial pressures when using different hard cervical collars: Stifneck, Philadelphia, Newport, and Miami J (24). The study found that the Newport and Miami J collars had lower skin capillary closing pressures, and their open-cell foam material prevented moisture accumulation. In supine and upright positions, the Philadelphia collar exerted high capillary closing pressures leaving the tissues susceptible to injury. In another study, occipital pressure, skin temperature, and humidity were compared when wearing the Philadelphia and Aspen collars (25). Measurements were taken at two separate time intervals, zero and 30 minutes. Using paired *t*-tests the authors found no difference in pressure or skin temperature with the two collars. Skin humidity, however, was higher when wearing the Philadelphia collar. Skin humidity relates to perspiration and perhaps the closed cell materials used in the Philadelphia collar caused the subjects to perspire more. For patients predisposed to excessive perspiration, the materials used in the collar's construction should be considered in order to optimize patient comfort, compliance, and minimize ulcer formation.

Additional but uncommon complications associated with the use of hard collars have included marginal mandibular nerve palsy (26), dysphagia (27), changes in intracranial pressure (28), reduction in tidal volume (29), and incomplete tetraplegia (30).

### Cervicothoracic Orthosis (CTO)

Several prefabricated hard collars (i.e., Philadelphia, Miami, and Aspen) can be made with an extension piece placed anteriorly and/or posteriorly to transform a CO into a CTO. For bedridden patients, devices without a posterior piece are better tolerated. CTOs restrict middle and lower cervical motion. Other examples of CTOs include the SOMI and Minerva. The SOMI is named for its body attachments: sternum, occiput, mandible immobilizer (Fig. 77-2). If the mandibular support interferes with the patient's ability to chew, or a pressure sore develops, or the patient has a prominent chin, a forehead strap attaching to the occipital support can be substituted. Since this device lacks posterior thoracic support it cannot limit extension; it does limit flexion, however. Furthermore, it may be an appropriate option for bedridden patients since it lacks posterior thoracic coverage. Because the SOMI limits flexion it may be used in cases of atlantoaxial instability with an intact dens, such as in patients with rheumatoid arthritis and in C2 neural arch fractures.

The Minerva is a total contact orthosis with fixation points at the chin, occiput, sternum, thorax, and the forehead. The jacket is made of polyethylene and lined with an open cell material. In addition to controlling the middle and lower cervical spine it can be used for the upper cervical spine below C2. In a study examining the effects of mastication on cervical motion in patients wearing a cervical orthotic, it was found that chewing while wearing a brace with a chin device increased motion above C4 (31). This has implications for patients wearing a Minerva brace while eating. Benzal et al. found that when comparing the halo to the Minerva, the average movement from flexion to extension was 3.7 degrees  $\pm$  3.1 for the halo and 2.3 degrees  $\pm$  1.7 for the Minerva, suggesting that the Minerva could be considered over the halo in injuries below C2 (32). Between the occiput and C1 the halo provided

**FIGURE 77-2.** SOMI. The SOMI is named for its body attachments: sternum, occiput, mandible immobilizer.

better stabilization (33). When comparing the rigid Miami J collar to the Minerva, the Minerva did not provide better control of the upper cervical spine (7). Greene and associates recommend using either a rigid collar or a SOMI for stable upper C-spine fractures (15).

There has been a published case report of the Minerva brace causing dysphagia with resultant aspiration pneumonia (34). The report outlined several mechanisms placing the patient at risk for aspiration pneumonia: head elevation, slight cervical extension, and limited chin tuck. These combined factors interfere with the swallowing mechanism in some patients. Mechanical changes affecting swallowing have been reported in healthy subjects wearing a Philadelphia, SOMI, and halo vests. Using video fluoroscopy, patients were presented with liquid and solid boluses. Mechanical changes such as alterations in swallowing initiation, reduced hyoid movement, narrowing of the pharynx, and pharyngeal residue were observed; aspiration was not (35). The proposed mechanism for the altered swallowing is related to the 90 degree head spine alignment caused by bracing. This study suggests that if this occurs in healthy subjects, those patients with disordered oral/pharyngeal mobility because of spinal cord injury and/or anterior cervical surgery may be at a greater risk for swallowing problems. An additional study found that mechanical dysphagia in healthy adult patients wearing a halo device was the result of cervical hyperextension (36).

### Halo Orthosis

The halo cervicothoracic orthosis (CTO) provides triplanar cervical vertebral motion control. While it offers significant restriction, intersegmental vertebral “snaking” has been described (37). “Snaking” is defined as flexion of one vertebral segment with extension of the adjacent vertebral body. It has been blamed for the motion occurring while immobilized. Koch and Nickel found motion for individuals wearing a halo averaged 31% of normal in the lower cervical spine with the greatest motion at C4-5 (37). Johnson et al. reported 4% sagittal and frontal motion and 1% transverse motion (3). Lind and associates also detected motion ranging from 2 to 17 degrees, with an average of 9 degrees between C2 and C6; the largest movement occurred between the occiput and C1 (38). One study attempted to reduce this intersegmental motion by inserting a posterior pad (39). Using 30 healthy volunteers, wearing a halo with and without a posterior pad attachment, spinal motion measurements were taken in supine and upright positions. The results revealed that the posterior pad did not prevent segmental motion.

The halo has been used postoperatively as an adjunct to internal fixation for upper cervical and mid-cervical fractures and dislocations and as the primary method for conservative fracture stabilization. Although it is the most restrictive appliance, it does not guarantee alignment or fusion. It does have several advantages: it provides immediate cervical spinal stability in patients sustaining an acute fracture or subluxation; it is a nonsurgical alternative for patients

refusing operative care or for whom surgical intervention is contraindicated; and it permits early mobilization without risk of compromising spinal alignment. Typically, it is worn for 3 to 4 months.

The basic halo vest components include a rigid open or closed back stabilizing ring fixed to the cranium by four skeletal traction pins with supporting rods and a superstructure that connects the ring to a fleece-lined plastic vest (Fig. 77-3). Instead of four skeletal traction pins, some neurosurgeons insert six traction pins into the cranium. Nemeth found that using six pins for fixation resulted in greater halo strength and cervical stabilization without increasing the occurrence of pin-site complications (40). More than four pin sites are used in pediatrics, patients with thin skulls, certain skull fractures or other conditions that compromise the usual fixation points. It should be noted that pin site complications are a frequent occurrence and require regular vigilant wound care. All current parts and vest designs are compatible with diagnostic imaging: magnetic resonance, computed tomography, or x-ray.

**FIGURE 77-3.** Halo vest.

In cases where emergency access to the thoracic cavity is required, such as to administer cardiopulmonary resuscitation, the vest can be opened. To open the vest, some designs require a specialized tool while others have quick release buckles or an integrated hinge system. The rehabilitation team should be familiar with how to open the vest. Laterally, the vest has straps that adjust the tightness across the torso. One study found that the strap tension influenced the degree of spinal motion (41). Increasing the strap tension decreased the motion, especially in lateral bending. No detectable differences were noted for extension. Clinically, the straps should be examined periodically to ensure adequate fit between the vest and thorax. Over the course of rehabilitation, changes in the person's body habitus are expected; for example, weight loss due to diuresis or changes in appetite can affect chest circumference, and strap adjustments may be indicated. Failure to monitor vest-thorax fit could compromise cervical stability offered by this external device. Trunk deformities may interfere with the patient's ability to tolerate such an intimate vest fit. Patients and caregivers should be strongly discouraged from arbitrarily manipulating these straps without consulting the physician.

A recent design variation to the standard whole torso vest is an adjustable four-pad (4PAD) thoracic vest (42). Instead of a two-piece vest, this orthotic consists of two lateral pads, one sternal and one thoracic spine pad. These pads move independent of one another. This design does not use shoulder straps. Fuki et al. evaluated this new product and found that it compared favorably in terms of patient outcomes and in its ability to immobilize the cervical spine despite its reduced torso contact (43). These pads do not interface with the clavicles, scapula, or abdomen thus improving patient comfort and reducing the incidence of pressure sore development. Fukui et al. found that the distraction loads were less than the "standard" vest type.

When identifying precautions for the halo vest, the physician should instruct the rehabilitation team to limit the patient's shoulder abduction to 90 degrees and avoid shoulder shrugging (37). Apparently, large distraction forces are generated with these therapeutic exercises. Such forces may pose a danger to the injured vertebral segment (37). In general, ample space should exist between the shoulders and the shoulder vest straps to prevent excessive distraction forces on the cervical spine. When this space is reduced, the shoulders press against the straps and changes in forces are created.

Care must be taken not to lift, turn, or move the patient by pulling on the plastic vest, the rods, or the superstructure. External forces applied to these areas could affect the spinal alignment and loosen pins. Pin loosening is defined as either a visible pin tip or when the pin can be manually rotated (44). In addition to external forces affecting tightness, there appears to be a natural decrease in compressive pin force over the duration of use (45). Subjectively, the patient may report clicking/grating/creaking sounds, a sensation of looseness, pain at the pin site, headache, or halo vest movement. Since pin loosening is the most frequent complication, all members of the rehabilitation team should be aware of these signs and symptoms.

Loose pins are either retightened or removed and reinserted elsewhere. Initially, the preferred pin placement is anterolateral above the frontal orbital rim and posterolateral below the largest diameter of the skull, the parietal occipital region (46). These positions prevent piercing the temporalis muscle and the frontal and temporal fossa and injury to nearby cranial nerves. If the temporalis muscle is penetrated, the patient will complain of increased pin site pain during mastication. Patients with a cranioplasty may be more susceptible to pin penetration and alternative safe positions for the pins may need to be identified prior to their insertion (47). A case report identified a patient who sustained an epidural abscess as a result of pin penetration through the temporal cranioplasty (47). In another case report, 11 years after the halo was removed, the patient developed tonic-clonic seizures (48). On investigation of the etiology, it was determined that the epileptic focus was the scar tissue caused by the pin penetration. In another case study involving a 71-year-old man wearing a Halo to manage an unstable fracture at C6-7 conservatively, epileptic seizures were developed after 8 weeks of wearing the vest. MR scan of the brain revealed pin penetration into the lamina of the skull with a subarachnoid hemorrhage (49). Vertullo et al. recommend tightening pins 24 to 48 hours after insertion and at 1 week (44). He found that it was a safe and effective method to decrease pin site complications.

Pin site infection is another common complication. To prevent infection, careful inspection for acute signs and symptoms of infection and prophylactic treatment should be ordered for the rehabilitation nurses. Olson recommends cleansing the sites using sterile cotton-tip applicators with antimicrobial soap and normal saline (50). Other topical cleansing agents such as povidone-iodine (Betadine), hydrogen peroxide, and alcohol have been associated with pin corrosion, interference with bacterial autolysis, ineffective infection reduction, and disruption of the healing process (50). Topical ointments can obstruct fluid drainage and increase the risk of infection; hence, prophylactic use is discouraged (51). Crusts surrounding the pins should be gently removed with a saline-soaked cotton-tip applicator. If left alone these crusts could cause fluid buildup predisposing the wound for infection (51). Pin site care should be performed daily. When crusts or drainage are present, it should be done more frequently (50). If drainage or erythema is present then laboratory testing for culture and sensitivity should be ordered to evaluate for an infectious organism. Patients being discharged to home with a Halo vest should be educated regarding proper pin site care. Those patients who are noncompliant with pin site care and develop an infection without follow-up with their physician may develop pin-site myiasis (maggots), a rare complication (52). To date there has been only one documented case in the literature.

In a case study by Rosenblum and Ehrlich (53), a 26-year-old man was treated with a halo secondary to a C6 burst fracture. One week after admission to rehabilitation, his right rear halo pin loosened and it was retightened. Pin care orders were for hydrogen peroxide three times a day. Four weeks later the right pin was loose with mild crusting. Subsequently, the patient presented with signs and symptoms

consistent with psychosis. MRI results were consistent with a brain abscess at the temporal-parietal junction. Bone and brain biopsy revealed *Staphylococcus aureus*. The patient was treated with systemic antibiotics. His psychosis resolved. This illustrates that changes in mentation may be a possible indicator of brain abscess in patients wearing a halo. Furthermore, other signs and symptoms such as scalp/pin cellulitis, headache, eye pain, fever, and seizures should alert the physician to consider brain abscess due to halo pins in their differential diagnosis. In another case study a brain abscess was diagnosed after the fixator was removed. Ray and associates treated a 53-year-old male post halo removal wearing a rigid collar who presented to their hospital with severe headaches, confusion, vomiting, and left hemiparesis (54). CT with contrast revealed a right parietal cerebral abscess. The abscess had developed under the previous halo pin site. In the presence of neurologic symptoms coupled with a past medical history of halo fixation, physicians must consider a cerebral lesion such as a brain abscess.

A prospective study evaluating bone mineral density changes in the cervical spine for patients wearing a halo found that the vest produced local osteoporosis in the immobilized vertebra (55). The reduction in bone mineral density, however, was not related to the level or type of cervical injury, age, or gender of the patient. At the 5- to 6-month follow-up, the local vertebral osteoporosis was mostly reversible.

In preparation for discharging a patient to the community with a halo vest, the patient and caregivers should be aware that the halo has an effect on balance and gait. In a study evaluating balance impairments in young healthy subjects wearing a halo, the authors discovered that their subjects' balance was compromised (56). Kazuicchio et al. found that wearing a halo vest altered gait kinematics, stride length decreased whereas stride time increased (57). The vest also reduced normal motion between the shoulder girdle and the trunk, the pelvic girdle and the trunk and decreased hip motion. Since there is less motion between the shoulder girdle and the trunk, arm swing is reduced. These gait changes are compensatory strategies for impaired balance. It was concluded that wearing the halo vest affects the gait speed causing the patient to walk slower. This certainly has implications for geriatric patients who frequently have underlying equilibrium impairments. In fact, their cervical injury could have been a result of a fall. Intrinsic and extrinsic factors related to prevention of falls should be explored prior to discharge. Home modifications to eliminate potential fall hazards should be discussed (e.g., removal of scatter rugs, installation of stair rails, wearing proper footwear, etc.). A home visit conducted by the inpatient rehabilitation team or a home care therapist should occur to evaluate the discharge environment and make safety recommendations to prevent falls in patients wearing a halo vest. In light of the slow walking speed, physicians should advise the inpatient rehabilitation and home care therapist to educate the patient regarding safe street crossing procedures and to conduct community ambulation training. Numerous other complications have been associated with the use of the halo device (46–62). Table 77-4 outlines complications associated with the halo orthoses.

**TABLE 77.4** Complications Associated with Halo Vest Use

- Loss of spinal reduction while wearing a halo
- Failure to develop spinal stability after wearing the halo
- Pressure sore development
- Pin loosening
- Pin site pain
- Pin tract infection
- Brain abscess
- Local osteoporosis
- Acute equilibrium impairments
- Forehead scarring
- Dysphasia
- Pin penetration of the skull
- Halo ring migration
- Cranial nerve palsy
- Brachial plexopathy
- Reduction in vital capacity
- Periorbital edema
- Cervical muscle atrophy
- Epileptic seizures

In response to the complications caused by the insertion of Halo pins into the cranium to achieve skeletal fixation, an alternative design was proposed: the Lerman Non Invasive Halo (LNIH). It is compatible with diagnostic imaging, including x-rays, CT, and MRI. The design consists of a padded anterior carbon composite chest plate with two posts attached to an open ring, the open ring corresponds to the traditional halo ring, with a nonallergenic silicone material adhering the ring to the skin, occipital, and mandibular supports with posterior straps that secure the anterior thorax plate in place. This device has been used in adults and children. In pediatrics, the indications for use are: immobilization of a stable fusion, reduction of C1-2 rotatory subluxation, postoperative cervical positioning following sternocleidomastoid release for congenital muscular torticollis, and in patient who fail standard Halo use (63). Complications associated with its use are facial swelling and skin breakdown. In a small study, three adult patients, who sustained a traumatic nondisplaced or minimally displaced fracture and were neurologically intact, were safely managed with this device during their acute hospitalization (64). No long-term outcome studies are available. As a whole there is very little published research about this orthotic device; however, it holds promise as an alternative to skeletal fixation.

## THORACOLUMBOSACRAL ORTHOSES

The thoracolumbosacral orthosis (TLSO) is a spinal orthosis that provides fixation at the extremes of the pelvis and the shoulders in an attempt to immobilize the thoracolumbar spine in varying directions. All trunk orthoses produce their desired effect by applying anterior abdominal compression, restricting trunk/intervertebral motion, and supporting/aligning the

spine, as previously discussed. Although exact mechanisms are unclear, abdominal compression results in increased intracavity pressure, which leads to a reduction in the lumbar lordosis and a decreased load on the vertebrae and intervertebral discs. Nachemson showed reduction in intradiscal pressures by 25% with both a corset and a rigid brace (65). Studies to assess the brace efficacy are limited by the methods used to assess motion limitations, (i.e., x-ray, fluoroscopy, EMG, strain-gauge), the patient population compared (healthy, back pain, whiplash, fracture, or postoperative) and the outcome measure (pain relief, fusion, functional improvement, ROM). Nonetheless, the ability of different devices to produce a desired effect is believed to depend on how restrictive they are in design and in materials. The effectiveness in limiting intersegmental motion of the thoracic, lumbar, and sacral spine in all three planes has been studied repeatedly though not as extensively as that of COs. Dorsky and associates found various types of orthoses effective in controlling lateral side-bending as compared to flexion-extension motion (66). Cholewicki et al. compared three TLSOs, the Aspen, the Boston Body Jacket, and the CAMP in normal subjects and found no significant difference in restriction of motion or amount of passive stiffness, but noted that the Aspen was significantly more comfortable (67). Krag et al. also found no significant difference between the Boston and the Aspen on most motion restriction but again the Aspen was rated more comfortable (68). The custom-molded TLSO resulted in the most gross body motion restriction and the corset resulted in the least (69). All TLSOs have been shown to be more effective in reducing motion at the upper levels than at the lower levels, with greatest motion at the lumbosacral joints (70–72). With three-column injuries, none of these braces were able to adequately limit motion (73).

Myoelectric activity of erector spinae muscles, while wearing various spinal orthotics, has been investigated with inconsistent results. Lantz et al. compared the lumbosacral corset, the chairback, and a molded TLSO. Overall, the TLSO reduced the myoelectric signal activity the most (74). Cholewicki showed only a small reduction in lumbar EMG trunk muscle activity with the LSO (75) and Krag showed no difference (68).

### Thoracic and Lumbosacral Spine Biomechanics

The thoracic spine can be thought of best by dividing into upper (T1–4), middle (T5–8), and lower (T9–11) segments and the lumbar spine as the thoracolumbar junction (T12–L1), mid-lumbar (L2–4) segment, and the lumbosacral junction (L5–S1). The 12 thoracic vertebrae are limited in motion in all directions by their attachment to the ribs and orientation of the facet joints; they are further limited in extension by overlapping of their spinous processes. As one moves in a cranio-caudal direction, the range of sagittal plane flexion-extension motion increases. The coronal plane (lateral) flexion-extension motion and axial rotation increases to the maximum degree at the lower thoracic and thoracolumbar junction, and then decreases again. At the thoracolumbar junction, the curvatures of kyphosis and lordosis change direction, the facet joints change direction from frontal to sagittal plane, the gravity

FIGURE 77-4. Jewett brace.

line bisects the T12–L1 disc and there is the weakest muscular protection. As a result, this area is considered the most mobile segment and is prone to traumatic injuries. The lower lumbar segments, L4–5 and L5–S1, are more susceptible to herniated discs and spondylolisthesis (76).

The TLSOs can be divided into categories based on the direction of motion they control: flexion, flexion-extension, flexion-extension-lateral, and flexion-extension-lateral-rotary control orthoses.

### Flexion Control Orthosis

The flexion control orthosis is also referred to as an anterior hyperextension brace, which functions to extend the thoracolumbar region. It is prefabricated and lightweight. The Jewett and cruciform anterior spinal hyperextension (CASH) braces are examples of this type of orthosis (Figs. 77-4 and 77-5). Both use a three-point pressure system without any abdominal compression. The Jewett brace consists of a metal anterior and lateral frame. Attached to the frame are two lateral pads, a sternal pad, a suprapubic pad, and a posterior thoracolumbar pad. The pads exert pressures over a small area and therefore may cause discomfort. The CASH orthosis consists only of an anterior metal frame that is shaped like a cross with the pads attached at the ends. The horizontal bar is attached at the midpoint. It is easier to don and doff than the Jewett and is better tolerated. Both are designed to prevent only flexion and do not limit lateral and rotary movements. They have been used to aid in the treatment of osteoporosis and anterior compression fractures. However, they have not been found to decrease kyphosis and have been found to cause excessive hyperextension forces on

FIGURE 77-5. Cash brace.

**FIGURE 77-6.** Taylor brace.

the posterior elements, inducing fracture. They are contraindicated in unstable fractures or in cases where extension must be prohibited, such as spondylolisthesis.

### Flexion-Extension Control Orthosis

The Taylor brace, designed in 1863, for the treatment of Pott's disease, consists of two thoracolumbosacral posterior uprights attached inferiorly to a pelvic band and superiorly to an interscapular band that also serves as an attachment for axillary straps (Fig. 77-6). Anteriorly, there is a corset for abdominal compression. The axillary straps extend over the shoulders and pass under the axillae, buckling at each end of the interscapular band. This brace limits the trunk extension, primarily in the mid-to-lower thoracic and upper lumbar areas with a compensatory increase in motion at the upper thoracic, lower lumbar, and lumbosacral junction. The straps must be tight in order for the brace to be effective and thereby may cause shoulder pain limiting the patient's compliance. In addition, the straps may restrict end-range shoulder motion.

### Flexion-Extension-Lateral Control Orthosis

The Knight-Taylor brace is a combination of the Knight (described later) and the Taylor brace (described above). It adds a pair of lateral uprights to the design in an attempt to limit lateral trunk motion (Fig. 77-7).

### Flexion-Extension-Lateral-Rotary Control Orthosis

This is similar to the Knight-Taylor brace except that the interscapular band is extended anteriorly and superiorly, and

**FIGURE 77-7.** Knight-Taylor brace.

subclavicular pads are added. Called the cowhorn orthosis, it has the added benefit of limiting trunk rotation and flexion in the thoracic and upper lumbar spine; however, it can also cause a compensatory increase in motion at the lower lumbar spine and lumbosacral junction.

### Plastic Body Jacket

The custom-molded plastic body jacket is the orthotic apparatus of choice when maximum immobilization is necessary (Fig. 77-8). Fabricated from polypropylene through a plaster cast taken from the patient, body jackets provide total contact to soft tissues with reliefs over bony prominences, thereby distributing forces over a large area for greater comfort, support, and motion control. The superior and inferior portions of the anterior section restrict flexion in the thoracolumbar and lumbosacral segments. The superior and inferior forces from the posterior shell and the forces from the abdominal area in the anterior component resist extension. The upper and lower portions of the lateral aspects of the jacket limit lateral trunk motion. And lastly, these forces combine to limit the thoracolumbar rotation. Abdominal compression also alleviates pressure on the vertebrae and discs and reduces myoelectric activity of erector spinae musculature.

Proper fit requires that the inferior border of the anterior shell rest one-half inch above the pubic symphysis, the trim follows the inguinal fold when the patient is sitting, and the superior border encompasses the sternal notch. If the anterior-inferior border is too long, the patient will have difficulty sitting forward and performing sit-to-stand transfers, as the brace would block the forward motion required to transfer. If during transfer training, as the therapist attempts to guide and position the trunk forward in preparation to transfer, the patient complains of pain in and around the pubis, the orthotist must be contacted to trim the brace. Posteriorly, the shell should extend from the spine of the scapula to the sacrococcygeal junction with the upper gluteal mass contained and the axillae and trochanter free (77). Extra precautions must be taken when fitting a jacket to an insensate patient; however, since the jackets are total contact in design, they are better tolerated. Plastizote lining and ventilation holes make the jackets even more comfortable and breathable. They can be washed and modified as needed; they

**FIGURE 77-8.** Custom-molded body jacket.

can even be modified to accommodate a drain. The jackets can be made into lumbosacral orthoses (LSOs) and cervical thoracolumbosacral orthoses (CTLsOs) when the upper thoracic spine needs immobilization. They should be worn at all times when on an incline greater than 30 degrees, though this is often modified by the surgeon (e.g., to allow the patient to shower). Foam designs with rigid stays may be beneficial in those cases where postural forces exacerbate curves and positioning is the main desired goal. Restrictions of activity and brace wearing must be individualized for each patient's needs.

## LUMBOSACRAL ORTHOSES

The LSO may be either flexible or rigid. The flexible LSOs refer to corsets, belts, and binders. While not effective in restricting motion to a significant degree, they can elevate intra-abdominal pressure, thereby unloading the spine and supporting structures (77), and provide inhibitory kinesthetic feedback and warmth. The rigid LSOs are categorized in the same fashion as the TLSOs, namely by the motion they control; in this case flexion-extension, flexion-extension-lateral, and extension-lateral. A pneumatic orthosis, called the Orthotrac, is a newly designed LSO being used now for low back pain patients. Dallolio studied 41 patients with radicular low back pain using this pneumatic vest and showed a 78% reduction in pain (78). More studies need to be undertaken to assess its efficacy.

### Flexion-Extension Control Orthosis

The chairback brace is a rigid LSO that consists of two posterior uprights attached to a pelvic band inferiorly and a thoracic band superiorly, with an abdominal support fastened to the posterior uprights with straps. The thoracic band should rest just below the inferior border of the scapula and the pelvic band at the sacrococcygeal junction. Its forces serve to restrict flexion and extension and also provide abdominal compression when the abdominal support is tight.

### Flexion-Extension-Lateral Control Orthosis

Also known as the Knight brace, it further limits motion with lateral uprights added to the chairback brace (Fig. 77-9). The lateral bars pass over the iliac crests so they must be fitted carefully to avoid pressure on these bony prominences.

FIGURE 77-9. Knight brace.

FIGURE 77-10. Williams brace.

### Extension-Lateral Control Orthosis

The Williams orthosis limits extension and lateral motion but encourages flexion (Fig. 77-10). Its effect is to reduce the lumbar lordosis. It consists of pelvic and thoracic bands joined by a pair of lateral uprights (no posterior uprights), which decreases the lateral motion. The thoracic and lateral bars are directly attached to each other but the pelvic band is attached to the lateral upright with oblique lateral bars that pivot at the top but secure rigidly at the bottom. The abdominal support is elastic and an adjustment strap between the pairs of uprights acts as a lever to pull the oblique uprights more posterior and decrease the lordosis.

### Corsets and Binders

When treating low back pain, flexible LSOs are the most prescribed spinal orthoses. These are garments made of typically prefabricated fabric, which are closed in the front with Velcro or laces and encircle the lumbar and abdominal areas. Designs vary and include the lumbar/abdominal binder, the Warm-N-Form, and the lumbosacral corset (Figs. 77-11 and 77-12). The latter can be further modified to include posterior stays and shoulder straps.

The binder is elastic and must be wrapped tightly around the lumbar and lower abdominal area in order to elevate intra-abdominal pressure. A common error in donning the binder is placing it above the diaphragm. The addition of a thermoplastic insert (Warm-N-Form) molded to the patients' lumbar curve and inserted into a posterior pocket may provide increased support and feedback.

FIGURE 77-11. Lumbar binder.

**FIGURE 77-12.** Lumbosacral corset.

The lumbosacral corset is longer than the binder, with the anterior-superior border extending to just below the xiphoid process and the inferior border to just above the pubic symphysis. Posteriorly, the borders go from below the scapula to just below the gluteal fold for women and gluteal bulge for men. The garment needs to fit all body contours snugly. As with other spinal orthoses, continued use will result in weakness and atrophy of trunk muscles and an exercise program needs to be given to the patient concomitantly. In addition to its use for pain relief, it provides postural, vasomotor, and respiratory support in cases of paralysis. In patients with paralysis and respiratory insufficiency, it places the diaphragm in a superior position and can assist the patient with increased diaphragmatic expansion.

## SACROILIAC ORTHOSES

Sacroiliac orthoses include trochanteric belts, sacral belts, and sacral corsets. They are prefabricated devices that wrap around the pelvis between the iliac crests and greater trochanters. They are differentiated by the height of their superior borders, their adjustability, and materials. They may have perineal straps attached to prevent upward displacement and a sacral pad to apply pressure over the sacrum (Fig. 77-13). While minimally effective in restricting motion, they may increase the intra-abdominal pressure and provide kinesthetic feedback to maintain a neutral pelvis. These devices can help to stabilize the sacroiliac joint, support pelvic fractures and traumatic

**FIGURE 77-13.** Sacroiliac corset.

sacroiliac joint separations, decrease sacroiliac joint pain and pregnancy-related (79) and postpartum pain.

## CLINICAL USES FOR SPINAL ORTHOTICS

Spinal bracing is a common modality used for treatment in a variety of conditions affecting the spine (Table 77-5). There are no definitive recommendations when choosing a particular orthosis for a given condition and considerable variability exists among practitioners. An in-depth discussion of each condition identified above goes well beyond the scope of this chapter. Nevertheless, certain general principles apply.

If motion restriction for pain relief is the goal, and stability is not in question, as in cases of arthritis, sprain, strain, degenerative disc disease, osteoporosis, and even tumors or infections without neurologic impairment or instability, then corsets, collars, and binders may be adequate. This must be balanced with mobilization and proper exercise. The length of its use must be discussed with the patient and tailored based on variables such as age, concomitant conditions, and chronicity of complaints. A review of the literature by Resnick et al, regarding the prophylactic use of lumbar braces for the prevention of low back pain, suggested Class 3 medical evidence that these supports do not reduce the incidence of low back pain or decrease the amount of time lost from work in the general population. When used in those workers with a history of low back pain, there was a decrease in the number of work days lost due to pain. For acute low back pain, their use was effective; however, for the chronic back pain population

**TABLE 77.5** Orthotic Treatment of Clinical Conditions

Sciatica
Degenerative disc disease
Herniated nucleus pulposus
Radiculopathy
Spondylolisthesis—congenital and degenerative
Spondylosis
Osteoarthritis—facet joint arthritis
Traumatic fractures—compression, burst, fracture-dislocation
Osteoporosis—kyphosis, compression fracture
Spinal fusion
Laminectomy or discectomy
Inflammatory arthritis—rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis
Infectious diseases—spinal osteomyelitis and abscess, tuberculosis
Spinal tumors
Paralysis—tetraplegia, paraplegia
Spina bifida
Scoliosis
Cervical and lumbar sprain
Torticollis
Whiplash

their use was not. This review also felt that if a brace was used for the chronic back pain population, rigid braces had more benefit than soft ones (80). In cases of spondylolysis and low back pain, Iwamoto showed that conservative treatment with rest and lumbosacral bracing was satisfactory in controlling symptoms (81).

In cases requiring orthoses for spinal stability, flexible devices are not adequate. In cases of vertebral fracture and trauma, spinal level and degree of injury must be ascertained. Treatments may include surgical stabilization, bracing, or both. Controversy in treatment exists in deciding which fractures have enough stability to be treated in an orthosis alone versus those in which surgical stabilization is needed. Denis described instability in 1984 (82,83) based on the three-column spine with instability defined as it relates to the integrity of the middle column. While some base their evaluation of stability on the presence of injury to the posterior elements (84,85) and others on the structural integrity of the middle column's bony as well ligamentous structures (86), Denis' theory was supported by Panjabi et al. in 1995 (87) and is generally accepted. Other conditions considered unstable generally follow these same principles with variability due to needs of the specific patient.

First-degree instability (Denis type I) is seen in compression fractures. In these cases, only the anterior column is affected. The middle column's structural integrity remains intact and is therefore considered a stable fracture. Conservative treatment will suffice in the majority of these injuries and tends to include hyperextension bracing or body jacket. When the compression is 30% or less, no external support is required, and early ambulation was reported to be as effective as bracing intervention (88). Orthosis had no effect on back pain or eventual disability in a retrospective review by Folman and Getstein, in stable thoracolumbar fractures with kyphosis less than 20 degrees and compression less than 50% (89). There exists, however, a subset of these lesions that can progress and lead to a posttraumatic kyphosis. According to Ferguson and Allen (90), this occurs when the compression is greater than 50% of the original body height and is the result of posterior ligamentous injury. Frequent monitoring is required. Tezer et al. believe that compression fractures with kyphosis greater than 30 degrees require evaluation of the posterior ligamentous complex and if damaged then surgery should be considered even in the neurologically intact patient (91).

Second-degree instability is typical of the burst fracture (Denis type II), a compression injury of the anterior and middle columns. These fractures may behave more like fracture/dislocation injuries, making categorization in terms of "burst" variable. This has resulted in considerable controversy in treating these fractures. Nevertheless, two-column instabilities that are neurologically intact can be treated conservatively with a Jewett, CASH, or custom-molded TLSO appliance (92,93). Wood et al. in a prospective study, found that operative treatment of thoracolumbar fractures provided no major long-term advantage compared with nonoperative treatment with bracing (93). Fractures with posterior element instability (three-column injury) will likely require surgery.

Seat belt injuries (Denis type III) may heal (about 50% of these injuries) with a hyperextension TLSO if the fracture line passes through bone, the so-called Chance fracture (94). However, if the fracture passes through the soft tissues, known as a slice fracture, then surgery is required. Fracture/dislocation injury (Denis type IV) is an unstable fracture and frequently results in paralysis. This always requires surgery unless there are other contraindications (73).

After decompression and/or fusion procedures for degenerative disease, the literature varies on the need of bracing. Few studies deal with the subject and none with an adequate study design to support or refute their use. No reliable information is available on the effectiveness of bracing for improving fusion rates or the benefit of clinical outcomes. While it is possible that some fusion patients may benefit, our ability to select a patient is poor (95). Following surgery for fracture or ligamentous injury, the literature again varies. In both cases, bracing will depend on the type and location of the fracture, if present, the procedure performed, any underlying spinal pathology and mostly on the personal views of the surgeon (96).

In any of these cases, the patient may participate, if needed, in a rehabilitation program to address mobility, activities of daily living, and community reentry. The patient should also be instructed in any restrictions of activity, donning and doffing of the brace, cleaning of the brace, and proper skin care. A T-shirt should be worn under the TLSO to protect the skin, and the orthosis must be donned tightly, otherwise the stabilizing effect is diminished (73). It is usually best to don a TLSO while in the supine position in order for it to be aligned properly.

# Wheelchairs

Freedom of movement is an essential component of human independence. In the Institute of Medicine model on the enablement/disablement process (1), a wheelchair and its components are fundamental for altering the interaction a person with a mobility limitation has with the environment. Not surprisingly, studies in various populations and cultures have repeatedly shown that mobility is closely tied to quality of life (2–6). It is therefore critical that the physiatrist takes an active role in the wheelchair prescription process. Fundamental to this role is knowledge related to the understanding of the complex components that make up seating and wheelchairs.

Seating and wheelchair technology has become increasingly complex. In this chapter, the readers will find information to help them gain an understanding for differentiation among various types of manual and power wheelchairs, and seating systems. In addition, newer hybrid wheelchairs, such as power add-on units, are discussed. The importance of the wheelchair-user interface, ride comfort, durability, selection of accessories, and powered-wheelchair control devices is also stressed. The readers are introduced to wheelchair and seating measurements and a variety of cushions and postural supports.

## **PRESCRIPTION PROCESS**

### **Team Approach**

The complexity of wheelchair and seating components combined with the nuances of individuals and various disease processes make it virtually impossible for a single clinician to act independently when prescribing assistive technology for mobility. For this reason, it is important to involve an interdisciplinary team in the decision-making process (7). The most important team member is the patient. The opinions and desires of the patient are critical to a successful fitting but must be assessed in terms of their level of knowledge and insight. Some patients have been using a wheelchair for years and know exactly what they are looking for. For these individuals, team members act to provide unbiased information. Alternatively, a novice patient may have little knowledge of what is available and the trade-offs of each decision. For this individual, the team will need to be more directive. The family and caregiver should also provide input, as they will be the next most affected by the choice of wheelchair.

The assessment team can consist of a variety of rehabilitation professionals (Table 78-1). Currently, Medicare and the majority of private insurance companies require a face-to-face physician assessment focused on mobility before providing a wheelchair. Given the training on function and mobility, a physiatrist can be the most appropriate physician to complete this assessment. Often an occupational or physical therapist working with the physician will conduct an evaluation. Ideally, the therapist will be certified by The Rehabilitation Engineering and Assistive Technology Society of North America (RESNA) as an assistive technology practitioner (ATP). Other professionals who can be certified and may be part of the team include a rehabilitation engineer, an Assistive Technology Supplier (ATS), or Certified Rehabilitation Technology Supplier (CRTS, National Association of Rehabilitation Technology Suppliers).

Those involved in the wheelchair selection process should have knowledge about the technology available on the market. Magazine articles and commercial database sources such as ABLEDATA (<http://www.abledata.com/>) and SpinLife ([www.spinlife.com](http://www.spinlife.com)) are good places to research devices or to direct patients who want to educate themselves. (As with any medical advice, patients should be cautioned that information gathered from TV, internet, magazines, etc., should be confirmed with their physician, therapist, or technology supplier.) People choose their seating and mobility devices based on the features available that will facilitate activities or address needs (8); therefore, it is important to be aware of the user's preferences and the features of various devices.

### **Patient History**

The interview process is largely the same as any standard history conducted with a patient. The necessary information such as age, past medical history, and current medical diagnosis needs to be gathered. The assessment process involves obtaining critical information about the user and his or her environment, family support, and past use of assistive technology. It is essential to determine if the individual's physical impairment is changing rapidly or is stable. It is important to establish the diagnosis that requires the wheelchair and to assure that there are no ongoing medical problems or complications that can affect the wheelchair prescription and the patient's health.

To properly specify a wheelchair, it is important to understand both the intentions and the abilities of the user (9). It is essential that the clinician takes into account the characteristics

**TABLE 78.1** Members of the Seating and Assessment Team

- Patient
- Rehabilitation engineer
- Occupational therapist
- Physical therapist
- Rehabilitation technology supplier
- Speech and language pathologist
- Rehabilitation physician

of the intended user and potential caregivers to ensure that the wheelchair will be accepted and used by the user. Access to a range of heights might be important to reach objects in the home and other environments. To support vocational needs, specific requirements may exist for mobility within a laboratory, operating room, courtroom, or machine shop. Leisure activities, pursued in such places as community centers, restaurants, movie theaters, and recreational environments, often place the most demands on the wheelchair. For some users, many of the desired tasks may be accomplished simply and with existing off-the-shelf technology. Others will require custom products, and some will not be able to achieve all of their goals with existing technology.

Additional necessary information includes type of insurance, physical capabilities and if the individual is able to transport a wheelchair. Also, if the patient has been using a chair, historical information about his or her current chair should be addressed, including problems he or she may be having. The wheelchair model chosen should also be compatible with the user's public and private transportation needs (such as a bus, train, car, van, or airplane) and home/Activities of Daily Living (ADL) environment.

The surface conditions may impose restrictions on the type of wheelchair that is most appropriate. The regularity of the surface and its firmness and stability are important in determining the tire size, drive wheel location, and wheel diameter. The performance of the wheelchair is often dictated by the need to negotiate grades, as well as height transitions, such as thresholds and curbs. The clearance widths in the environment will determine the overall dimensions of the wheelchair. A scooter may not fit around a corner in an average person's home but might perform well outdoors on a sidewalk. The need to be able to operate in snow, rain, and other weather conditions are important considerations as well.

### Physical Examination

With an understanding of the individual's need or desire to perform different activities, the next step is examining the user. The history likely provided significant insight related to his or her physical abilities. To verify this, a physical examination should focus on aspects of the patient that will help (a) justify the wheelchair and seating system, (b) determine the most appropriate wheelchair and seating system, and (c) assure that medical issues are appropriately addressed. Based on the interview of the patient, it may be possible to omit some portions of the examination listed below.

Often individuals require a wheelchair because of cardiopulmonary disease. For these individuals it is important to document a heart and lung examination. Attention should be paid to dyspnea on exertion and changes in vital signs with activity. These findings can be used to justify a power wheelchair, as the energy cost of wheelchair propulsion is not less than walking (10). Other common reasons for requiring a wheelchair are musculoskeletal and neurologic deficits. The clinician should document the neurologic and musculoskeletal deficits in a methodical fashion. In a patient with a stroke, for example, an examination to check for neglect or visual field deficit is important because it will impact on the ability to independently drive a chair.

Obvious examination items include strength and range of motion. For individuals with chronic arthritis problems, the examination should document the painful, swollen, or malaligned joints. When no strength deficit is seen, it is important to document issues with coordination, tone, and proprioception. For example, a study by Fay et al. found that many individuals with multiple sclerosis were unable to effectively propel manual wheelchairs due to increased tone and decreased coordination (11). Participants showed an inability to maintain a speed comparable to community walking speed (1 m/s). This type of finding can provide justification for the device selected.

While completing the examination, the physician should be thinking about how the individual will control the wheelchair. If there is poor hand coordination, head control or switch control may be needed. In certain cases, a foot joystick may be possible.

For some individuals, the examination and history will not necessarily establish a clear need for a wheelchair. In these cases, it is important to consider alternative options that meet the individual's functional needs.

It is important to establish how long the individual will be using the chair. If from the history and examination it is determined that the deficit will be transient, then a rental chair may be appropriate. Medicare will rent chairs for their beneficiaries. This is a good option if the duration of use will be short and the device does not need to be customized. If during the history and physical examination medical issues that require intervention are identified, it may be appropriate to delay wheelchair prescription so that changes in the patient status do not necessitate changes in the prescription. In such case a rental may provide short-term mobility.

Stability can be assessed by observing the individual in the current wheelchair or by asking him or her to sit unsupported on a mat table. Ask the patient to perform simple reaching tasks to determine the lateral and forward stability of the trunk, hand and arm strength, and hand fine motor skills. The presence of kyphosis, scoliosis, or other fixed deformities should be determined. Critical point to evaluate is hip and knee range of motion because contractures may need to be accommodated. Poor stability usually indicates the need for special attention to seating and position. Appropriate seating can enhance reach and stability, thus improving the performance of manual activities from the wheelchair. It is well known that various groups of wheelchair users, such as individuals with tetraplegia and cerebral palsy, will develop kyphosis or scoliosis over time (12).

TABLE 78.2 Medicare Recommended Documentation Items

- Symptoms
- Related diagnoses
- History
  - How long the condition has been present
  - Clinical progression
  - Interventions that have been tried and the results.
  - Past use of walker, manual wheelchair, scooter, or power wheelchair and the results
- Physical exam
  - Weight
  - Impairment of strength, range of motion, sensation, or coordination of arms and legs
  - Presence of abnormal tone or deformity of arms, legs, or trunk
  - Neck, trunk, and pelvic posture and flexibility
  - Sitting and standing balance
- Functional assessment
- Any problems with performing activities including the need to use a cane, walker, or the assistance of another person
  - Transferring between a bed, chair, and wheelchair
  - Walking around their home—to bathroom, kitchen, living room, etc.—provide information on distance walked, speed, and balance

What is less well known is whether spinal deformities can be prevented with appropriate seating. Even if prevention is not a goal, accommodation is needed for comfortable seating.

Finally, a thorough check of the individual’s skin is important. This may not be needed for individuals with cardiopulmonary disease, but it is essential for individuals with neurologic deficits or those with previous history of pressure sores. The examination should include not only the buttocks but also the feet and calves, which can be affected by pressure against a leg rest. Attention should be paid to bony prominences and previous scars. This examination will help with cushion selection and wheelchair setup. Large, previously untreated ulcers are sometimes discovered, ultimately leading to treatment before seating plans can be implemented.

For many people a few simple measurements can be used to determine the proper dimensions for a wheelchair (13). Body measurements are typically made with the consumer in the seated position. Probably the most obvious body measurements are the consumer’s height and weight. The consumer’s weight is critical to obtaining a wheelchair that is sufficiently strong as many wheelchairs are only rated to hold up to 113 kg (250 lb). The height of the wheelchair user provides information about the person’s size and can be used to check the final wheelchair measurements. For example, the sum of the sitting height, sitting depth, and lower-leg length should be close to the person’s supine height. Additional measurements and definitions are used when specialized seating and postural support systems are required. These measurements may be completed by any one of the team members.

Documentation

Providing appropriate and quality wheelchairs requires well organized and often extensive documentation. At the very least,

a prescription and various insurance forms must be provided. For more expensive and complex interventions, a letter of medical necessity (LMN) is required. Table 78-2 list Medicare recommended assessment findings for power wheelchair provision. This letter can consist of two components: a cover letter and the “client/patient evaluation and intake form.” The cover letter summarizes the person’s disability, problems with existing equipment or method of mobility, evaluation procedures, conclusions, explanation of why lower-cost alternatives will not work, risks of not providing the equipment, and a line-item justification for each of the various components being recommended. The “client/patient evaluation and intake form” guides the evaluation process and captures in-depth information of the evaluation findings required to support recommendations of the appropriate seating and mobility interventions. Often, a part of this exam will be completed by an occupational or physical therapist. The therapist will perform clinical trials and simulations, which allow the patient to try many different devices.

The prescription process should include a home assessment to make sure the device selected will work in the home environment. A home assessment conducted by the supplier is required by Medicare. This requirement highlights the importance of working with qualified suppliers such as those with the ATS credentials. If a home visit is conducted, documentation of the visit should be included in the LMN.

In order for any health insurance provider to approve coverage for a wheelchair and seating system, the practitioner must establish and document medical necessity. Each funding source may have its own definition of “medically necessary,” however; in general, when it comes to wheelchairs, it is necessary to accommodate or replace a malfunctioning body part (i.e., paralysis or weakness of the lower extremities) or to reduce or manage disability. Many funding sources also require

the recommended intervention to be the least costly, reasonable alternative. Therefore, as part of an evaluation, it is helpful to document that lower-cost alternatives have been tried and were unsuccessful, and to cite specific reasons for the higher-cost choice. It is also helpful to document the potential outcomes if the person is not provided with the equipment. Examples of these risks include falls and fractures, development of pressure sores, joint contractures and musculoskeletal deformities, increased pain and discomfort, loss of function, and ultimately being more restricted to a bed or chair.

The final letter is reviewed by both the therapist and physician and cosigned. It is not appropriate for a physician or a therapist to sign the LMN for a client/patient if he or she has not evaluated the person for the device prescribed.

### Follow-Up

It is important that the delivery and the final fitting of the device is documented and verified by a follow-up visit with the team or one of the team members. This visit provides the client with the support of the team to be comfortable with the final acceptance and approval of the device and supports the supplier with appropriate clinical delivery documentation. Finally, this visit can be used to refine the patient's wheelchair driving skills to enable safe operation.

## MANUAL WHEELCHAIRS

Manual wheelchairs offer many advantages over powered mobility. Manual wheelchairs are much easier to transport because of their lighter weight. No special equipment is needed to place a manual wheelchair in a backseat, and individuals with paraplegia and tetraplegia are often capable of transporting their wheelchairs independently without additional technology. In addition, manual wheelchairs generally require less maintenance than power devices, and there are no concerns related to batteries or controllers. Finally, manual wheelchairs offer a degree of physical exercise that can benefit the wheelchair user.

### Depot and Attendant-Propelled Wheelchairs

The depot or institutional wheelchair is essentially the same wheelchair that was produced in the 1940s. This type of chair corresponds to the Medicare category of K0001 and, despite its numerous shortcomings, is the default chair for many insurance companies and Medicare. Today's depot wheelchairs may be a bit lighter than the 1940s models, but the basic frame design is unchanged. Depot wheelchairs are intended for institutional use, where many people may use the same wheelchair. These wheelchairs are typically used in airports, hospitals, and nursing care facilities. They are inappropriate for active people who use wheelchairs for personal mobility, including older persons in nursing homes. Depot wheelchairs are designed to be inexpensive, to accommodate large variations in body size, to be low maintenance, and to be attendant propelled. Unlike the attendant-propelled chairs described

**FIGURE 78-1.** K0001 depot-style wheelchair.

below, depot chairs are designed neither for the comfort of the person being transported nor for the person pushing the chair. A typical depot wheelchair will have swing-away footrests, often removable armrests, a single cross-brace frame, and solid tires (Fig. 78-1). Depot wheelchairs have sling seats and back supports, which are uncomfortable and provide little support. Swing-away footrests add weight to the wheelchair; however, they make transferring into and out of the wheelchair easier. Armrests provide some comfort and stability to the depot wheelchair user and can aid in keeping clothing off the wheels. Depot chairs typically fold to reduce the area for storage and transportation. Solid tires are commonly used to reduce maintenance. Solid tires typically dramatically reduce ride comfort, increase rolling resistance, and add weight. There is very little, if anything, that can be adjusted to fit the user on a depot chair. Typically, only the leg-rest length is adjustable. Depot chairs are available in various seat widths, seat depths, and backrest heights.

### Attendant-Propelled Chairs

Not all wheelchairs are propelled by the person sitting in the wheelchair. In many hospitals and long-term care facilities, wheelchairs are expected to be propelled by attendants. In addition, some individuals with severe disabilities are unable to propel a wheelchair or control a power wheelchair. For children who use attendant-propelled chairs, it is necessary to continually reassess if they may be able to use independent mobility. The primary consideration in the attendant-propelled chair is that the wheelchair has two users: the rider and the attendant. If the wheelchair is propelled solely by attendants with no assistance from the rider, then there may be no need for the larger drive wheels (Fig. 78-2). To keep the attendant comfortable, the weight of the chair should be kept as light as possible and the push handles adjusted to the height of the attendant. If the occupant will be sitting in the chair for prolonged periods of time, then attention must be paid to comfort. For this reason, attendant-propelled chairs often have tilt-in-space as an option.

**FIGURE 78-2.** Attendant-propelled wheelchair with tilt-in-space.

A variant of the attendant-propelled wheelchair is sometimes called a “Gerry” chair in reference to geriatric users. This type of attendant-propelled wheelchair is typically designed to make transfer out of the chair difficult. The rider is seated in a large recliner-type wheelchair. The soft padding, reclined position, small wheels, and large size make it impossible for the rider to move the wheelchair and difficult for most riders to exit the wheelchair. This helps long-term care facility to exercise control over their clients with cognitive dysfunction. There has been considerable discussion about the appropriate use of attendant-propelled chairs that significantly restrain the rider’s independence.

### Lightweight and Ultralight Wheelchairs

The terms *lightweight* and *ultralight wheelchairs* are derived from the Medicare categories K0004 and K0005, respectively. K0004 wheelchairs must weigh less than 34lb without footrests or armrests, and K0005 must weigh less than 30lb without foot or arm supports. K0004 wheelchairs have very limited adjustability (Fig. 78-3). Like depot chairs, they can be sized to the user, but many of these chairs do not offer features such as adjustable axle plates, quick-release wheels, or a method to change the seat to back angle of the wheelchair. Because of the way Medicare reimbursement works, manufacturers attempt to build the best wheelchair possible under a certain Medicare reimbursable cost. Unfortunately, this practice of cost engineering does not necessarily lead to improvements in design. In addition, this Medicare policy may cause dealers to push wheelchair users toward K0001 and K0004 chairs which have higher profit margins.

The ultralight wheelchair is the highest-quality chair that is designed specifically as an active mobility device (Fig. 78-4). These chairs, which can easily cost more than \$2,000, are usually highly adjustable and incorporate numerous design features made to enhance the ease of propulsion and increase the comfort of the wheelchair user. When made of titanium or high strength aluminum, this chair can easily weight less than 20lb.

**FIGURE 78-3.** K0004 lightweight wheelchair with folding cross-brace design.

At present, it is necessary to justify the need for a K0004 or K0005 wheelchair instead of a standard K0001. Unfortunately, the process of getting prior authorization—meaning the vendor is guaranteed ahead of time to be reimbursed for the wheelchair—is cumbersome. As a result; vendors are unwilling to take the risk that a \$2,000 item will be rejected by Medicare and become their problem. Currently, Medicare allows vendors to ask for preauthorization of these chairs; however, few vendors take advantage of this opportunity.

**FIGURE 78-4.** K0005 ultralightweight wheelchair with cantilever design.

Ultralight wheelchairs usually have a number of options and adjustments that can be made to appropriately fit the user. Following is list of many of the components of chairs and options that are available. It is important to remember that every component adds weight to the chair. A balance must be reached between providing the optimal equipment to make the individual as functional as possible and to keep the chair as light as possible. Some of these options are also available on light-weight and depot type chairs; however, the components used on ultralight chairs are generally lighter and better in quality.

### Frames

There are two basic frame types: folding and rigid. Within these two frame types, there are a number of different varieties. The most common type of manual wheelchair frame is the folding cross-brace frame (see Fig. 78-3). When viewed from the back of the frame, the cross members form an X with a hinge located in the middle of the X. The chair is folded by pulling upward on the seat upholstery. Cross-member folding mechanisms are simple and easy to use. However, the wheelchair may collapse when tilted sideways, and the frame becomes taller when folded. Some chairs incorporate snaps or over-center locking mechanisms to reduce the problem of frame folding while on a side slope.

The most common rigid chair is the box frame. The box frame is named for its rectangular shape and the frame tubes that form a “box” (9). Box frames can be very strong and very durable. These frames can also be collapsed to relatively small dimensions. The backrest usually folds forward, and when used with quick-release wheels, the chair becomes a rather compact shape. An alternative to the box frame is a cantilever frame that can act a suspension element (i.e., there is some flexibility purposely built into the frame). These cantilever frames may also have fewer tubes and fewer parts and thus be more aesthetically pleasing (see Fig. 78-4).

Some manufacturers offer suspension elements on the frame. This is in part a response to evidence that vibration exposure in wheelchair users is excessive (14). Hinges are placed at the front of the seat, and elastic elements are placed at the back of the seat. The elastic elements act to provide some suspension. The flexible element for the suspension can use either metal springs or polymer dampeners. Elastic elements have not necessarily resulted in lower levels of vibration being transmitted to the user (15). In addition, the shock absorption can result in lost energy during propulsion. This can occur because the force generated by the wheelchair user during propulsion goes toward compressing the elastic elements rather than forward motion. Therefore, the decision to purchase a suspension wheelchair should depend on whether the patient prefers the drive, feel, and comfort of the wheelchair.

## COMPONENTS

A number of components can be attached to both manual and power wheelchairs. The following list is focused on manual

wheelchairs, but many of the components are found on power wheelchairs as well.

### Footrests

Most wheelchair users require support for their feet and lower legs. This support is provided by footrests. Footrests may be fixed, folding, swing-away (see Fig. 78-2), or elevating. The footrests must provide sufficient support for the lower legs and feet, and must hold the feet in proper position to prevent foot drop or other deformities. It is essential to assess limitations in knee and foot range of motion. Some users have very tight hamstrings, requiring that the feet be positioned closer to or under the front edge of the seat. This is difficult to accomplish in most configurations. Extending the knees out to accommodate the standard design of the footrest position in front of the seat results in a sitting posture with a posterior pelvic tilt and a tendency to slide forward in the seat. This is commonly seen in elderly people in nursing homes using depot-type wheelchairs.

The feet must remain on the footrests at all times during propulsion, and therefore some type of cradle is recommended. Some wheelchairs (primarily those with swing-away footrests) use foot stirrups behind the heels of each foot (see Fig. 78-2). However, for other wheelchairs, it is best to use a continuous strap behind both feet because the rider's feet sometimes come over the stirrups during active use. The frame should be selected and configured so that the feet sit firmly upon the footrests, with shoes on, without lifting the upper legs from the seat cushion. Footrests are commonly placed between 25 and 50 mm (1 to 2 in.) from the ground to ensure that sufficient ground clearance is maintained. Often, the footrests are the first part of the chair to come in contact with an obstacle (such as a door, wall, or another chair), so they must be durable.

Rigid wheelchairs often use simple tubes across the front of the wheelchair. By using a tubular rigid footrest, the wheelchair becomes stiffer and stronger (see Fig. 78-4). Rigid footrests are used during sports activities and work well for people who are very active in their wheelchair. Forward antitip rollers can be mounted to rigid footrests. This is helpful for playing court sports and reducing the risk of some forward-tipping accidents. Folding wheelchairs often use footrests that fold up and leg rests that swing out of the way to ease in transfers. Swing-away leg rests are not as durable as rigid ones. In some cases, manufacturers design swing-away leg rests that will flexibly bend on impact. This helps to absorb the energy of the impact and possibly prevent serious injury to the wheelchair rider. Elevating leg rests can be used for people who can not maintain a 90-degree knee angle or who need their legs elevated for venous return. Elevating leg rests make the wheelchair longer and heavier. This also has the effect of making the wheelchair less maneuverable by increasing the turning radius. Therefore, if elevating leg rests are needed, a power wheelchair should be strongly considered.

### Armrests and Clothing Guards

Armrests provide a form of support and are convenient handles to hold onto when the rider leans to one side or the other.

Armrests are also helpful when attempting to reach higher places. For example, some people use their removable armrests as a tool to nudge items off high shelves. Armrests are commonly used to perform a “push-up” to assist with seat pressure relief. However, this is not the preferred method of pressure relief because of the significant stress it puts on the upper extremity (16).

There are three basic styles of armrests: wraparound, full-length, and desk-length. Wraparound armrests mount at the back of the wheelchair onto the frame below the backrest in most cases. The armrest comes up along the back of the backrest supports and wraps around to the front of the wheelchair. The major advantage of this design is that the armrest does not increase the width of the wheelchair like the other types of armrests. Wraparound armrests are popular among active wheelchair users. The most significant drawback of this design is that the armrest does not serve as a side guard to keep the rider’s clothing away from the wheels; although a removable piece of plastic called a clothing guard can be attached to the wheelchair frame to prevent clothes from getting caught in the wheels.

Full-length and desk-length armrests are similar in design, the main difference being the length of the armrest. Full-length armrests provide support for nearly the entire upper arm. They are popular on electric-powered wheelchairs because they provide a convenient and functional location for a joystick or other input device. Full-length armrests make it difficult to get close to some tables and desks. This is why manufacturers produce shorter desk-length armrests. Both of these types of armrests include clothing guards to protect clothing from the wheels. These types of armrests are mounted to the side of the wheelchair and may add as much as 5 cm (2 in.) to the width of the wheelchair.

Armrests can be fixed or height adjustable. Height-adjustable armrests may move up and down to accommodate the length of the rider’s trunk and arms. Most armrests can be moved in order to provide clearance for transferring in and out of the wheelchair and to allow a person to lean over the sides of the wheelchair. Armrests are either removed or flipped back. Both styles commonly use a latch, which is operated by the user. It is important to have secure latches on the armrests because armrests form convenient places for people to hold onto when attempting to provide assistance. If the armrests and latches are designed properly, two people can lift the rider and wheelchair by holding onto the armrests. In some cases, armrests are designed to pull out if any upward force is applied to them. These are not intended to be used for lifting the chair. It should be noted that armrests could alter the way in which a person propels a wheelchair. The hands and arms must clear the armrest in order to reach the push rim. This can force the user into excessive abduction at the shoulder, which could be a risk factor for injury.

### Wheel Locks

Wheel locks act as parking brakes to stabilize the wheelchair when the rider transfers to other seats and when the rider

wishes to remain in a particular spot. When locked, they keep the wheelchair stable to allow the rider to push things from the chair. There are a variety of wheel locks used to restrain wheelchairs when transferring or parking. High-lock brakes, which are located near the front corner of the seat, on the upper tube of the wheelchair’s side frame, are most common; however, location can vary. High-lock brakes require the least dexterity to operate. Extension levers can be added for people with limited reach or minimal strength. Wheel locks are standard equipment on wheelchairs, and they are simple to mount if the wheelchair does not come equipped with locks from the manufacturer.

Wheel locks may be push-to-lock or pull-to-lock. Most people prefer push-to-lock because wheel locks are more difficult to engage than to disengage. Riders often find it easier to push with the palm than pull with the fingers. Low wheel locks are usually mounted to the lower tube of the wheelchair’s side frame. Low wheel locks require more mobility to operate. They also alleviate the common problem that is seen with high wheel locks of the user hitting his or her thumb against the lock. This problem can be addressed for high wheel lock users by selecting retractable (i.e., scissors or butterfly) wheel locks. The retractable type of wheel lock helps to prevent jamming the thumbs and can also accommodate a wide variety of camber angles. The major drawback of retractable wheel locks is that they are more difficult to use than other types of wheel locks. The wheel lock must be positioned properly with respect to the wheel in order to operate effectively. If the wheels are repositioned, then the wheel locks must be repositioned. Tire pressure also affects the locking grip of these wheel locks. Many active manual wheelchair users will choose not to use armrests or wheel locks. Although these devices can be convenient, any equipment added will increase the overall weight of the chair, making propulsion more difficult.

### Tires

A variety of options exist with respect to tires. The most common type of tire is pneumatic. These tires are lightweight and provide cushioning against impact and vibration from rolling over surfaces. This cushioning may increase rider comfort and improve wheelchair durability. Pneumatic tires are recommended for outdoor usage. The main downside of pneumatic tires is that they require maintenance and they can puncture. Tire pressure needs to be kept at a predetermined level because it is critical to rolling resistance, which can be related to risk of secondary injury associated with manual wheelchair use. A study has shown that when propelling on tires that were deflated by 50%, energy expenditure increased by 25% (17). Clinicians involved with wheelchair users should squeeze their patients’ tires to assure that they are keeping up with this important regular maintenance issue.

An alternative to pneumatic tires is solid inserts. These foam inserts fit into the pneumatic tire and replace the air-filled inner tube that would normally be there. They add some weight to the chair and may slightly worsen performance but are a good alternative for individuals who do not want to be

responsible for maintenance of air pressure. A less viable alternative is solid tires. These tires require no maintenance and are low in cost. Unfortunately, they make for an uncomfortable ride as all ground shocks are transmitted to the wheelchair user.

### Additional Features

Many additional features are available that are unique to manual wheelchairs.

#### Antitippers

Antitippers are often placed on wheelchairs to assure they do not tip over backward. These can inhibit the ability to climb curbs, but they do offer a measure of safety. It is suggested that these be ordered for all wheelchairs and then have the user take them off when they are comfortable with the stability of the chair. A new antitipper is currently being developed but not yet commercially available that allows the wheelchair user to perform a wheelies and other skills. This device is folded up to allow the wheelchair user to perform his or her necessary wheelchair mobility skills, however; if the wheelchair user falls too far backward, the antippers will extend and prevent the wheelchair user from falling backward (18).

#### Push Rims

A number of different push rims are currently available, and new styles are likely to be introduced into the market. Anodized aluminum rims are the current standard on most K0004 and K0005 chairs. Less expensive chairs may come with plastic push rims. For individuals with difficulty gripping the rim, alternative rims should be considered. These can include vinyl-coated rims, rims with projections (Fig. 78-5), and rims wrapped with surgical tubing. All of these rims have the advantage of increased friction, making it easier to push the chair forward. Unfortunately, this increased friction can lead to burns when the wheelchair user attempts to slow down the chair. There is ongoing research into advanced ergonomic push-rim designs that allow for easier propulsion as well as braking (19). For individuals who have good hand function,

**FIGURE 78-5.** Wheelchair push rims: **(left)** quad-knob or projection rim, **(center)** vinyl-coated rim, **(right)** anodized aluminum rim.

a push rim called the “Natural-Fit” (Three Rivers, LLC, Mesa AZ) (see Fig. 78-4) is an ergonomically designed hand rim that has been shown to decrease stresses placed on the upper extremity during wheelchair propulsion (19).

#### Wheels

The standard wheels on lightweight and ultralightweight wheelchairs have spokes. Plastic wheels can be used on low-end chairs. These increase weight and decrease performance. High-end wheels are now available with flexible spokes or with graphite and composite materials. A study performed by Hughes et al. (20) found that high-end wheels did not improve efficiency but did significantly improve comfort of the rider. These wheels can be easier to maintain than standard spokes and also offer improved aesthetics.

#### Caster Wheels

Caster wheels are available in a variety of shapes and sizes. Pneumatic wheels are larger than solid casters and may interfere with the footrests when turning. Pneumatics offers the advantage of easier propulsion over rough terrain and increased shock absorption. Many wheelchair users are using narrow rollerblade-type wheels which allow quicker turns and reduce rolling resistance. Unfortunately, they can get caught in sewer grates or other small obstacles. Adding an elastomer shock absorber “frog-legs” in series with the caster can provide a means of shock adsorption vibration reduction (15) (Fig. 78-6).

**FIGURE 78-6.** Suspension caster fork. The elastomer acts to absorb shocks.

### Push Handles

Push handles, also known as canes, are attached to the back of the chair with the primary purpose of making it easier for an assistant to propel the wheelchair. Canes can also be used by the wheelchair occupant to help with pressure relief. The wheelchair user can hook the arm around the cane and pull to raise the contralateral hip, even in the absence of strong triceps muscles. Canes can also be used to hang a book bag or backpack onto the back of the chair.

### Grade-Aids

Grade-aids are devices that attach to the wheel and allow it to roll forward but not back. In this manner, they can make it easier to roll up a hill. These should be considered for individuals who have upper-limb weakness and who must negotiate hills.

### Manual Wheelchair Selection and Setup

As stated previously, a number of the features described above and the adjustments described below are available only for ultralightweight wheelchairs. Best practice dictates that any individual who will propel a wheelchair as a primary means of mobility should receive this type of chair. The optimal setup for a manual wheelchair is described in the Clinical Practice Guideline (CPG) for preservation of upper limb function (16) (Fig. 78-7). The chair should be as narrow as possible without causing undue pressure on the thighs. Rear axle position should be adjustable to fit the user, as it can affect caster flutter, rolling resistance, stability, and control and maneuverability. With a longer wheel base or more rearward axle position, the chair has more stability; however, rolling resistance is increased (21), caster flutter is increased, and downward turning on side slopes is increased. These changes are primarily related to the proportion of the weight that is placed onto the back, or larger, wheels. As the rear wheels are moved backward, more weight is placed on the front casters. These smaller-diameter wheels have higher rolling resistance. The cadence of the propulsive stroke is also higher, with a more rearward axle position. This has been implicated in relating to risk of repetitive strain injury. A forward axle position has been found to be associated with improved propulsion biomechanics (21). Given these issues, the axle should be as far forward as possible, providing that the wheelchair user

**FIGURE 78-7.** Optimal manual wheelchair setup. Illustrations A-C show differences in the elbow flexion angle ( $Q$ ) from adjusting the height of the axle. Illustration B depicts the recommended elbow angle ( $Q_2 = 100$  to  $120$  degrees). Angle  $Q_1$  (illustration A) is smaller because the seat is too low (axle too high). Angle  $Q_3$  (illustration C) is larger because the seat is too high (axle too low).

still feels stable. Most wheelchairs come in a factory-set position, with the axle most rearward. This should be gradually adjusted forward to maximize performance of the chair.

Axle height, or the distance between the shoulder and the axle, is an important parameter that is also described in the CPG (16). If the seat is too high, the wheelchair user will not be able to reach much of the push rim and so they will push with shorter strokes and a faster cadence. If the seat is too low, the user will be forced to abduct at the shoulder during the propulsive stroke, which may cause rotator cuff impingement. In general, while sitting upright with the hands resting on the top of the wheels, the elbow angle should be between  $100$  and  $120$  degrees for optimal mobility (22,23). Alternatively, if the arms are left to hang freely at the side while sitting on the chair, the fingertips should be just past the axle of the wheel.

Camber describes the angle of the wheel with respect to the chair. Increasing camber has several advantages: the footprint of the chair is widened, creating greater side-to-side stability; it allows quicker turning; and positions the push rims more ergonomically for propulsion (it is more natural to push down and out). In addition, by having a wider based, the area where the hands are in contact with the push rims is less likely to come into contact with the wall (24). Finally, adding camber to the rear wheels reduces effective stiffness between the rolling surface and frame, thus reducing the vibration exposure of the user.

A disadvantage to increasing camber is also that it adds width to the chair. Generally, for daily use, the chair should be as narrow as possible without substantially diminishing the handling characteristics. The wheels should be offset enough from the seat to avoid rubbing against the clothing or body. Between  $2$  and  $4$  degrees of camber is appropriate for everyday use.

There are many other aspects of a wheelchair that can be adjusted to improve fit and performance. Some of these adjustments are discussed in the seating section that follows.

### Alternative Manual Wheelchairs

Two alternatives worth mentioning are chairs for amputees and chairs for individuals with hemiparesis. Wheelchairs for individuals with amputations are typically designed with the rear axle set far behind the user. This is needed because the absence of a leg causes the body's center of gravity to be shifted posteriorly, thus reducing rearward stability. Unfortunately, all of the negative aspects of a rearward axle are present. An alternative can be to add weight to the front of the wheelchair. Unfortunately, increased weight means increased rolling resistance. There is no simple answer as to what is best, and individual patients should make this decision for themselves.

For individuals with hemiparesis or other disability that makes propulsion with a leg or both legs superior to propulsion with the arms, a "hemiheight" chair is an alternative. In this chair, there is typically one footrest or none at all, and the seat is low enough to the ground so that the feet can reach the floor. For an individual with hemiparesis, the use of the

uninvolved arm and leg can provide limited, but functional, propulsion.

Another alternative for an individual with hemiparesis is a one-arm drive chair. This chair has two push rims on one side that control separate wheels. One-arm drives are heavier than standard chairs and can be difficult to control. These limitations make them less than ideal for an elderly stroke patient. Although not popular in the United States, lever-drive wheelchairs are seen in Europe. These chairs offer a mechanical advantage by using a lever to make propulsion more efficient (25). Unfortunately, they do not offer the direct proprioceptive feedback of hand rim contact and can be difficult to maneuver in tight spaces and when traveling backward. Lever-drive chairs are heavier and often wider than standard chairs.

### Manual Wheelchair Propulsion Technique

In recent years, much has been learned about the most appropriate way to propel a wheelchair. This has been learned by studies that have found an association between upper-limb injuries and wheelchair propulsion biomechanics (21). Manual wheelchair users should propel with long smooth strokes that minimize the cadence with which they push and maximize the length of the stroke or contact angle (16,21). The wheelchair user should attempt to impact the rim smoothly and match the speed of the hand to the rotating speed of the push rim. During the recovery stage of the propulsive stroke, the user should let the hand drop below the push rim and stay below the push rim until he or she is ready to begin propulsion again (26) (Fig. 78-8).

**FIGURE 78-8.** Recovery pattern. This represents data from a wheelchair user. The *dark circle* is the push rim. The *thinner lines* are from a marker placed on the wrist. This recovery pattern was found to provide the best efficiency. Direction of travel is left.

Wheelchair propulsion techniques can be evaluated using devices such as the commercially available SmartWheel (Three Rivers Holdings, LLC, Mesa, AZ). This is the only device on the market that can objectively evaluate wheelchair propulsion and is used at numerous centers. The device replaces one of the patient's wheels on his or her own wheelchair. The individual can then propel over various surfaces that he or she would encounter in normal life. The wheel measures parameters including peak force, push frequency, and contact angle. A database has been created in which a clinician can compare his or her patient's wheelchair propulsion performance against a larger group of wheelchair users (27). This device can also be helpful when making a decision if an individual should be using a manual wheelchair user (MWC) or a power wheelchair user (PWC), to evaluate propulsion mechanics, and as a wheelchair propulsion training tool.

### POWER WHEELCHAIRS

There is strong evidence in the literature to indicate that the use of powered mobility facilitates independence, improves occupational performance, and is correlated with a higher sense of quality of life for people who cannot ambulate or propel a manual wheelchair effectively (2,4,6). However, there are some disadvantages to powered mobility devices that need to be factored into the decision of powered versus manual wheelchair mobility (Table 78-3). Power wheelchairs come in a number of configurations. Two types are those with a power base and those with integrated seating systems. In general, wheelchairs with integrated seating systems are less expensive and offer less with respect to seating options.

#### Power Bases

The power base is the lower portion of a power wheelchair that houses the motors, batteries, drive wheels, casters, and electronics to which a seating system is attached (Fig. 78-9). The base allows for the mounting of any variety or combination of

**TABLE 78.3** Powered Versus Manual Wheelchair Mobility

Advantages of Manual Wheelchairs	Advantages of Power Wheelchairs
Transportation: Easy to transport; can travel with friends without special vehicles	Distance: Can travel long distances without fatigue
Maintenance: Can be worked on independently	Speed: Can travel at higher speed without fatigue
Exercise: Theoretical benefit to the user from using own force to propel	Terrain: May be able to traverse rougher terrain
Aesthetics: Less appearance of disability	Protect the arm: Avoid repetitive strain injuries that are due to manual wheelchair propulsion

**FIGURE 78-9.** Mid-wheel-drive power wheelchair with power base. The seating system can be removed and replaced with a different seating configuration.

different seating systems and seat functions, including tilt-in-space, reclining back, elevating leg rests, and seat elevator.

### Drive Classification

Power wheelchair bases can be classified as rear wheel drive (RWD), mid-wheel drive (MWD), and front wheel drive (FWD). The classification of these three drive systems is based on the drive wheel location relative to the system's center of gravity. The drive wheel position defines the basic handling characteristic of any power wheelchair. Each system has unique driving and handling characteristics. In RWD power bases (Fig. 78-10), the drive wheels are behind the user's center of gravity, and the casters are in the front. RWD systems are the traditional design, and therefore many long-term power wheelchair users are familiar with their performance and prefer them to other designs. A major advantage of an RWD system is its predictable drive characteristic and stability. A potential drawback to an RWD system is its maneuverability in tight areas because of a larger turning radius.

In MWD power bases (see Fig. 78-9), the drive wheels are directly below the user's center of gravity and generally have a set of casters or antitippers in the front and rear of the drive wheels. The advantage of the MWD system is a smaller turning radius to maneuver in tight spaces. A disadvantage is a tendency to rock or pitch forward, especially with sudden stops or fast turns. When transitioning from a steep slope to a level surface (like coming off a curb cut), the front and rear casters can hang up, leaving less traction on the drive wheels in the middle. However, manufacturers have addressed these shortcomings and have updated designs of MWD that now are available with a wheelbase consisting of six wheels

**FIGURE 78-10.** Rear-wheel-drive power wheelchair.

touching the ground; with two small wheels in the front and back. These wheels are equipped with suspension and shock absorbance systems that enhance forward stability and small obstacle climbing capability.

A FWD power base (Fig. 78-11) has the drive wheels in front of the user's center of gravity, and the rear wheels are casters. The advantage of an FWD system is that it tends to be quite stable and provides a tight turning radius. FWD systems may climb obstacles or curbs more easily as the large front wheels hit the obstacle first. A disadvantage is that an FWD system has more rearward center of gravity; therefore, the system may tend to fishtail and be difficult to drive in a straight line, especially on uneven surfaces.

**FIGURE 78-11.** Front-wheel-drive power wheelchair.

## Controls

The device that is used to control a powered mobility system is called an access device. The primary function of the access device is to drive the chair. Secondary applications are for use with environmental control systems and computer access. By using the same control interface for both the power wheelchair and the secondary systems, the seating position and control selection can be optimized for multiple functional purposes. The majority of input controls are programmable, allowing changes in speed and the amount of movement to determine the direction of the wheelchair. Many power wheelchair users brace some portion of their hand against the control box and use their hand and arm coordination to operate the joystick. Gross arm function, in many cases, can be used to operate a joystick. If the user does not have the hand function or coordination to operate a joystick input device, other options are available. Other parts of the body, such as the chin or foot, can operate a modified joystick.

The cognitive abilities required to operate an alternative control typically increase as the physical and functional abilities of the user decrease. Programmable wheelchair controllers allow reduction of the maximum velocity and modification of the acceleration and deceleration rates of the wheelchair. To assist persons with more severe cognitive or visual limitations, technologies are being developed that enable the wheelchair to follow walls, navigate through doorways, and stop when other objects are contacted (28). For persons with spasticity, particularly tremor in the hand, modern controllers have filters that can be adjusted to give smoother wheelchair control. Positioning technology enables the joystick to be placed in a variety of locations to optimize the user's ability to operate it (29).

## Joysticks

Joysticks are the most common access devices for powered wheelchair systems. Most joysticks are proportional; meaning the control's speed output to the wheelchair from the joystick is in proportion to how far the joystick is pushed from the center position. Research is being conducted on different input methods to control a joystick, one of which is an isometric joystick (30). Joysticks can be fitted with a template that only allows motion in certain directions. This is useful for people with poor motor control, such as can be seen in athetoid cerebral palsy.

The end of the joystick can also be modified for easier grip. One common modification is a goalpost shaped attachment (T-bar) with the upright section of the joystick on either side of the hand. Alternatively, a simple tennis ball cut to fit over a traditional joystick can make gripping easier.

## Mini Joystick

The Mini Joystick, a type of micro proportional joystick, maybe a good alternative for a user who has lost gross arm function, and is unable to use a conventional joystick but still possesses small distal motor function within the fingers.

The Mini Joystick has the same proportional and directional features of a conventional joystick; however, the tuning and the physical displacement of the joystick is scaled down and requires significant less effort to achieve small joystick displacement (i.e., wiggle of the tip of a finger). Its smaller size also permits more freedom in its placement to meet the functional/comfort needs of the user (i.e., custom fitted on a stable arm support for independent single finger control or custom fitted through the "horn" of a palmer support for thumb control). Its tuning and custom programmability capabilities allow head control drive option when faced with complete loss of upper extremity and lower extremity functions. Used as a chin interface, it requires minimal effort of facial and cervical musculature to operate the control.

## Sip-and-Puff

Sip-and-puff switches are used primarily by people with tetraplegia. A sip-and-puff access device consists of a replaceable straw located near the mouth. Pulling and pushing air through the straw with the mouth controls the wheelchair. These systems can be set up in a variety of configurations. Generally, the user will sip a specific number of times to indicate a direction and puff to confirm the choice and activate the movement of the wheelchair. It is common for an auxiliary visual display to be used with sip-and-puff to provide feedback to on which command was selected. Sip-and-puff is becoming somewhat antiquated now that microproportional joysticks, head array sensors, and gyroscopic-based joysticks are available.

## Switches and Buttons

An array of switches or a single switch can be used to control a chair. The more switches, the greater the motor control needed to operate the equipment. Using scanning, a single switch can control a wheelchair. In scanning, choices are presented to the user on the wheelchair controller. When the desired choice is presented, the user activates the switch to select that command. Two switches can fully control a wheelchair in a fashion similar to the one described above for sip-and-puff systems. An array of switches can be used for quicker control. There is no proportional control of the wheelchair's speed with switched control. Thus, users are forced to travel at the same, rather slow velocity at all times.

Many of the input devices described in this section can be used for more than the control of the wheelchairs only. Two common additional uses are environmental control and computer access. In some cases, the computer is mounted to the wheelchair, but often it is at a fixed site. A critical consideration when selecting or designing a user interface is that the ability of the user to accurately control the interface is heavily dependent on the stability of the user within the wheelchair. Often custom seating and postural support systems are required for a user interface to be effective. The position and stability of the user interface are also critical to its efficacy as a functional access device.

### Considerations in Selection of Electric-Powered Mobility

There are many considerations in defining the correct power wheelchair for a given individual. Important factors include the means of transportation of the wheelchair surface conditions the chair must negotiate, need to negotiate thresholds and curbs, and clearance widths in the environment. In addition, subject preference is important, as well as maximum speed and range. Typically, a wheelchair will be used on a daily basis and, as such, has a life expectancy of 3 to 5 years.

### SEATING AND POSITIONING

Seating systems can be organized into three general categories: off-the-shelf systems, modular systems, and custom-molded systems. Overlap exists between the categories, and a given seating system should be prescribed and designed specific to the user's medical, functional, and personal preference needs. The simplest form of seating system is a linear seating system that involves a planar seat and back with fixed angles and orientations.

Medically, a system should address issues of soft-tissue management, comfort, reducing the potential for or accommodating orthopedic deformities, and maintaining vital organ capacity. Functionally, the system should address the movements and supports the user needs to reach or access objects, transfer, get under tables, and perform activities of daily living. The chair must become an extension of the user's body, much like an orthosis. This requires careful matching of critical chair dimensions to body dimensions, user abilities, and intended uses. The user's preference as to one system over another should be paramount in the prescription process. For example, a user may choose to forgo pressure relief and comfort for a firmer seating system that provides greater stability and allows him or her to have a firm surface to slide on the seat for ease with repositioning when transferring in/out of the device.

### Soft-Tissue Management

Soft-tissue management is a concern for all people who sit for prolonged periods of time and who have compromised sensation or the inability to perform weight shifts. External

causes of skin breakdown or pressure sores include excessive prolonged pressure over bony prominences, friction and shear, as well as heat and moisture. Intrinsic factors include the inability to move, poor nutrition, vascular problems, and the loss of soft-tissue elasticity (31). The loss of sensation is a key factor because discomfort is the usual trigger for shifting and moving. Because the causes of pressure ulcer vary, the choice of seat cushion will vary based on the client's risk factors and the characteristics of the cushion.

The fit of the wheelchair also contributes to pressure distribution. Footrests mounted too high increase the pressure over the ischial tuberosities. Properly adjusted armrest height allows weight to be distributed through the upper extremities. The angle of the back, relative to the seat, affects the stability and orientation of the pelvis and is reflected in how much a person will slouch, and the slouch posture affects pressure over the sacrococcygeal regions.

### Material Properties of Seating Systems

Cushions are chosen based on their characteristics, which are related to the properties of the materials used in their construction. Materials specific to those used in the design and manufacture of seating systems have certain characteristics, as shown in Table 78-4. Manufacturers make cushions that possess these qualities using flat and contoured foams, air-filled bladders, combinations of air and foam, flotation, viscous fluids, contoured plastic honeycombs, custom-contoured foam, and alternating pressure systems. These cushions vary in efficacy of pressure distribution, provision of postural stability, ability to insulate or conduct heat, and the reliability of their performance over time. Finding a cushion with good airflow and pressure distribution would be important for an immobile client who perspires heavily or is incontinent. Alternately, for a client prone to pressure ulcers, a practitioner would identify cushions with optimal redistribution of peak pressures. Active manual wheelchair users may not like an air-filled cushion because it does not provide a stable base for propulsion-related activities. If all the needed features cannot be found in one cushion, trade-offs are necessary. Research evidence supports that a properly fitted pressure-reducing cushion, in contrast to a low-cost foam cushion, reduces the probability of a pressure sore (32).

**TABLE 78.4** Characteristics of Materials Used in the Design and Manufacture of Seating Systems

Property	Application
Density: The ratio of mass or quantity of material to the volume of the cushion	A cushion filled with air will be much lighter than one composed of gel. Weight may be a problem for someone who has to lift it or propel a manual wheelchair.
Stiffness: The strength of the resistance to compression	Foam has low stiffness and does not resist body weight compared with a solid seat base. A solid surface provides greater pelvic stabilization; foam may allow better pressure distribution.
Thermal characteristics: The ability of the material to insulate or conduct heat	Dense foam cushions retain body heat. Honeycomb-designed cushions hold less heat. Gel and fluids tend to pull heat away from the body.
Friction: The ability to maintain position and to reposition if needed	Cushions with solid bases and slick covers make sliding in lateral transfers easier but may promote sacral sitting.

### Pressure Mapping

Pressure-mapping technology estimates interface pressure. A thin mat with pressure sensors is placed between the client and the seating surface. The mat connects to a computer and presents data in both graphic and numeric forms. As part of a skilled clinical assessment, it can be predictive of potential risk for pressure sores (33). This technology can help a clinician decide which cushion provides the best pressure distribution for a particular client. It is important to remember that pressure-mapping devices do not measure shear forces, heat, moisture, postural stability, or maintenance of the cushion. These factors must also be considered.

### Custom-Contoured Seating

Custom-contoured seating systems are necessary when all available off-the-shelf or modular seating systems cannot address the needs of the individual. This may occur in individuals with moderate to severe fixed and semiflexible structural deformities of the spine and extremities. In addition, individuals who require significant off-loading of soft tissue because of pressure sore issues may need a custom-contoured seat.

Custom-contoured seating involves a process of capturing a specific mold of a person's body. The mold can be obtained through several methods, including liquid foam in place, plaster molds, or through computer aided design/computer aided manufacturing (CAD/CAM) with greater control and accuracy. CAD/CAM usually involves the use of a seating simulator composed of bead bags for the seat and backrest supports. The bead bags are manually and gravitationally contoured around the shape of the person's deformities or pressure points, followed by vacuum evacuation of the air from the bags to produce a rigid mold. This mold is then scanned, using sensors that send data to a robotic milling machine for the production of a positive mold.

Custom-molded systems are not capable of correcting deformities. Careful skin inspections should be performed, and pressure-mapping systems should be used as appropriate to verify that the custom-molded seat contours are applied properly. Inappropriately applied contours can lead to pressure sores. Careful consideration of transfer technique is needed with these seating systems because proper positioning in the seat is essential to performance, and the custom contours usually make transfers more difficult.

### Back Support

A back support should conform to the normal spinal curvature while allowing movement as required by the user. The typical back support in a folding-frame wheelchair is sling upholstery, not because it is good back support, but because it bends to allow the chair to fold. Sling seats provide little in the way of support. The sling-back support stretches before a propulsive force is effectively applied to the rim, resulting in inefficiencies during wheelchair mobility. In individuals with tetraplegia, the stretching of the sling back can mean that the wheelchair user adopts a more posterior tilt of the pelvis, and this may contribute to a kyphotic spine (12). Like cushions, wheelchair

backs are chosen based on the client's seating goals. For clients with truncal weakness, the stability from a contoured backrest with or without modular lateral supports is needed to maintain head and neck position. Some clients may only need the soft contouring of an adjustable tension sling backrest, whereas others with significant kyphoscoliosis may need a custom-molded backrest to enable sitting in a more upright posture. Clients with this level of weakness or deformity will most likely use this seating in a powered mobility base or an attendant-operated base.

### Recline and Tilt-in-Space

Recline and tilt-in-space technologies relieve pressure, manage posture, provide comfort, and help with personal care activities. Recline helps stretch hip flexors and also assists with attending to catheters, toileting, and dependent transfers. Because reclining the seat back creates shear, the user often shifts in the wheelchair into a sacral-seated position. For a patient who is unable to reposition without help, adding tilt may help the user reposition independently. Tilt-in-space keeps the hip and knee angles constant when tilting the client back. Unlike reclining systems, the position of the user is maintained in the tilt seating system. It is essential that subjects who are unable to independently shift weight, unable to transfer independently, or have pain as a result of prolonged sitting, have a tilt-in-space and recline system on their chair (34). Tilt-in-space is also necessary for individuals with progressive disorders (34). An individual with amyotrophic lateral sclerosis may find it easy to perform weight shift and repositioning at an initial evaluation, but this can change quickly, leading to the need for modifications. Tilt and recline are also available in manual wheelchairs. For the most part, these chairs are only used for patients who require attendant control. As in recline, tilt-in-space greatly reduces pressure on the ischial tuberosities by shifting the pressure to the back. Several recent research studies support the combination of tilt-in-space and recline together. Using a combination of tilt-in-space and recline will maximize the function of both devices, enhance the ability of the individual to use the system for positioning, perform personal care tasks, reduce pressure and increase comfort (34).

### Other Positioning Systems

Stand-up wheelchairs are an alternative that deserves mention. The benefits of standing for individuals normally unable to do so may include decreased bladder infections, reduced osteoporosis, and decreased spasticity (35). In addition, there are likely psychological benefits that result from the feeling of upright posture and the ability to interact at eye level (36). Certain people cannot use a stand-up wheelchair because they do not have adequate joint range of motion. Some of the benefits of a stand-up wheelchair can be obtained by using a variable-seat-height wheelchair. The most common function of variable-seat-height wheelchairs is to provide seat elevation. A seat elevator has many useful functions that will improve the quality of life of the user. The device can help individuals avoid positioning their hand above the shoulder which can

help to reduce shoulder pain (37). The individuals will be able to reach heights that would have been impossible in the past, thus increasing independence. By allowing the individual to change his or her seat height, an easier, down hill, transfer can be performed. A downhill transfer may be beneficial because it can decrease the forces placed on the upper extremity (38). Finally, a seat elevator will allow the individual to interact with peers at eye level, thus improving the individual's ability to interact in a social situation. Seat elevators are strongly recommended by the CPG on preservation of upper limb function (16) and have been advocated by RESNA (39). Finally, some newer chairs offer lateral tilt-in-space. This feature allows the user to be leaned to either side and offers an alternative for people with difficult pressure sore or pain issues.

### Seating Setup

Setting up the wheelchair is critical to optimizing performance. A therapist or rehabilitation supplier working with the clinic commonly performs this. Seat height can be adjusted on most chairs. The seat height is dependent on the total body length of the user. Users with longer leg lengths will require higher seat heights to achieve sufficient clearance for the footrests. There is some flexibility when selecting seat height, even for taller individuals, because most active users prefer some seat angle or dump. Dump is achieved by tilting the seat down toward the backrest, thus the end closest to the backrest is lower than the front of the cushion. Dump allows the user to fit more securely in the chair, increasing the user's trunk stability and making the chair more responsive to the user's body movements. Seat depth is determined from the length of the upper legs. Generally, no more than a 75 mm (3 in.) gap should be between the front of the seat and the back of the knees when the person is in the wheelchair. This will help ensure broad distribution of the trunk weight over the buttocks and upper legs, without placing undue pressure behind the knee. Some gap is required to allow the user some freedom to adjust his or her position. Seat width is determined from the width of the person's hips, the intended use, and whether the person prefers to use side guards. Generally, the wheelchair should be as narrow as possible; thus, a chair about 1 in. wider than the user's hips is desirable.

### Power-Assisted Wheelchairs

A developing class of wheelchairs provides a power assist when desired, but allows the user to push the wheelchair as one would with a manual wheelchair. Power-assisted wheelchairs (Fig. 78-12) have force/moment-sensing push rims that provide an additional torque to the rear axle proportional to the applied moment. Such devices have potentially important benefits, such as allowing individuals to perform tasks faster and easier. In addition, people who normally would need to use a power wheelchair are able to self-propel a power-assisted wheelchair despite obstacles such as steep ramps (40–42). Finally, when using a power-assisted wheelchair, oxygen consumption and heart rate are significantly lower (43). For individuals with upper-limb pain or tetraplegia, the power-assisted

**FIGURE 78-12.** Power-assisted wheelchair.

wheelchair may prove to be a good compromise between a manual wheelchair and a power wheelchair. Before a power-assisted wheelchair is recommended to a client, it is essential that the client tries the device in his or her actual environment. Subjects may report that they encountered difficulty transferring from the chair equipped with power assist and in disassembling the power-equipped chair for transport. One study has shown that performing wheelchair skills that require great control, such as performing a wheelie or navigating the chair in small spaces, is more difficult with a power-assisted chair (44). Another study of individuals using power assist in their real-life environment did not show a significant difference in the amount of time individuals used the device and the distance they traveled (45). It is important to remember that under current Medicare guidelines, a power-assisted device will not be funded unless the patient has used a manual wheelchair for 1 year. This should not prevent recommending the device, but must be kept in mind when producing the LMN.

### Scooters

Scooters (Fig. 78-13) are another option for certain individuals. These devices typically have a single front wheel for steering and two drive wheels in the back. Possibly because scooters are available to help shoppers in many large department stores, they seem to have a greater degree of social acceptability than wheelchairs. This leads many clients to request these devices. Steering is accomplished via hand bars that are intuitive to users who have previously used a bicycle. Seating is provided in a chair having foam padding typical of a car seat. The backrest height ends at the level of the shoulder blades, which allows for unencumbered rotation of the trunk.

Scooters have a number of advantages and disadvantages that must be critically considered when prescribing this device

**FIGURE 78-13.** Scooter.

(Table 78-5). In general, scooters are a reasonable option for individuals who retain some ability to ambulate, such as those with cardiopulmonary disease limiting the ability to walk. Scooters are a poor option for individuals with progressive neuromuscular disorders because they have few options to accommodate progressive disability. They are also a poor choice if one needs to stay in the chair all day because seating options are limited. If a scooter is found to be the appropriate device, it is important that the scooter is trialed in the patient's home environment. Scooters require a large turning radius and often do not fit well into a person's home.

### Power Wheelchair Training

New wheelchair users should go through a wheelchair-training program. Wheelchair users can first practice basic maneuvers in controlled environments, then transition to uneven surfaces and slope transitions (i.e., level to sloped surfaces) in both the uphill and downhill directions and maneuvering through tight environments. Once these skills are mastered, they should gradually tackle more challenging environments,

such as steep grades and step transitions that exceed Americans with Disabilities Act (ADA) Accessibility Guidelines. The rider should always practice with an appropriate lap belt (46) and chest support in place, and a spotter (therapist) to assist if needed.

## PEDIATRICS

In many ways, the seating and mobility needs of children with disabilities are similar to those of adults. Comfort, stability, and function are paramount, and there is no one perfect position for every activity or situation. There is a tendency to be aggressive with children and force them to sit upright with many postural supports in the hope of preventing or delaying deformities. This tendency in the design of the seating system may force postures that are not tolerated or desired over time. It is important to seek input from both the child and the caregivers who will be dealing with the seating system on an hourly basis. Several variables in system design need to be considered with children, including developmental status, mobility, growth, age-appropriate activities, school, therapies, the environment, and family issues. Children not only change in size but their disability also often changes as they grow, even in nonprogressive disorders such as cerebral palsy.

### Pediatric Seating Systems

Pediatric seating systems can be classified in the same manner as outlined for adults in the previous section, with off-the-shelf, modular, and custom-molded systems available. The issue of growth should not be overvalued over function or other points of concern. There are some systems that can accommodate growth to a certain degree; however, these modular systems tend to be heavier and bulkier than the lighter, more compact, off-the-shelf systems or custom system that cannot change with growth. Clinicians need to consider the impact on current function of a heavier system and make their recommendations accordingly. It is possible to justify a new chair in a shorter period of time based on growth.

In certain cases, such as when a child lacks muscle control, modular systems can offer advantages. Trunk lateral supports may need to be removed while the child is engaged in a dynamic reaching activity or in therapy working on trunk control, but replaced to sit more passively when he or she fatigues. A child should also be allowed to passively sit when focused on other activities, such as schoolwork, or relaxing while riding in a vehicle or watching television. If the child has to focus all his or her energy on balance and stability, then he or she will have no energy to devote to the task at hand. If a seating system is too confining or restrictive with multiple supports, the child may fight the system to be able to move and be dynamic. Thus, the pediatric seating specialist must find a balance between appropriate amounts of support without overly restricting movement. An anterior chest harness or support may be needed for stabilization during transportation but removed to engage in schoolwork. It is important to educate

**TABLE 78.5** Scooters

Advantages	Disadvantages
Lower cost	Less stability
Easier to assemble and disassemble for transportation	Require greater arm strength and control to drive
Better than some chairs at rough terrain	Fewer seating options
Less perceived stigma of disability	Poor turning radius Must transfer out of chair for many activities

all parties as to when a certain support is appropriate and when it is inappropriate. Inappropriate use of chest harnesses has resulted in strangulation when the child slid down in the seat because he was becoming uncomfortable and trying to fight the restrictions of the seating system (47). It is often difficult to find a balance between providing enough support and still allowing for some freedom of movement. Having systems that are modular and flexible, as well as educating caregivers, can help find this balance.

Custom-molded are indicated when a child's postural deformities are so severe that they cannot be supported by a modular or off-the-shelf seating system. Custom-molded systems are not as common with children as they are with adults, as children's deformities tend not to be as severe. As with off-the-shelf systems, custom-molded systems have no growth capabilities.

## Mobility

Mobility is the precursor to all childhood development. Children need to explore their environment to know where things are and how to get them. The need for specific types of mobility bases, such as strollers, self-propelled systems, and powered systems, will depend on the age and the physical, developmental, and functional capabilities of the child, as well as the environmental and transportation resources of the family. Very young children may need a seating system that can be transferred and attached to a variety of bases for different activities. For play, children want to be close to the floor near their toys and peers. For eating, they need to be up where a caregiver can have access. Some manufacturers make seating systems that can be transferred to various mobile and stationary bases that are height adjustable. For example, one seating system can be transferred between a folding-style stroller type base, a higher eating base, and a power-wheelchair base and can also serve as crash-tested car seat.

There has been a historical tendency to push children with disabilities to ambulate with braces and other aids. The practitioner, however, needs to consider the mobility needs of the child, including the expected surfaces and distances. A manual or power wheelchair may be more efficient and actually provide greater independence. Children often abandon cumbersome upright ambulation in favor of a wheelchair when they are able to make their own choice. Consider a child with cerebral palsy trying to ambulate with braces and crutches as well as carry a bag full of books through a crowded hallway. Manual wheelchairs are sometimes a useful option for children; however, the weight of the chair may be an issue. Even an ultralightweight manual wheelchair weighing 20 lb is going to be heavy for a 30 to 40-lb child. Proper chair selection and training are essential to the long-term health of the child.

Powered mobility is important for children who cannot effectively self-propel a manual system; however, families often do not have the resources or psychological readiness either to make the necessary home modifications or to purchase an accessible vehicle that can transport a powered system. Research and clinical intuition indicate that children without cognitive disability should be offered mobility devices such as

power wheelchairs or adapted ride-on power toys as early as 12 to 18 months—about the time able-bodied children begin moving on their own (48–50). Even with a power wheelchair, there is often the need for a transportable folding supportive stroller-type base, as described previously, for use in family outings.

## Psychosocial and Family Issues

There are many psychosocial and family-related issues practitioners need to be cognizant of and respect. Having a child with a birth or acquired disability can devastate a family. Initially, there tends to be focus on the search for a cure to the problem, and the family may be a reluctant to accept use of a wheelchair, place a ramp in front of the home, or purchase a van with a ramp. The practitioner needs to counsel the family regarding the realistically expected short- and long-term outcomes of the child's situation. There is also a tendency to “care for” a child with a disability, especially in certain cultures and religions. It is common for children with disabilities to develop learned helplessness and for parents to develop a codependency in the relationship with their child (51). Later in life, this can result in lack of ability to make decisions or function in society. Children with disabilities need to experience the same stages of development—including successes as well as failures—as their able-bodied peers within the norms and values of that culture. Practitioners again need to counsel families so that they can effectively use this equipment to facilitate development and promote active participation by the child as appropriate based on their current and potential capabilities.

## STANDARDS AND DURABILITY

International standards are applied to mobility devices. The standards are formulated by ISO, the International Standards Organization; the American National Standards Institute; and by RESNA (52). The standards concern many aspects of wheelchairs, including electrical systems, durability, dimensions, flammability, strength of armrests, ability to withstand an impact, and stability, to name a few. These standards can be requested from the manufacturer and can serve as a method of comparing classes of wheelchair as well as individual wheelchairs to each other. Wheelchair users should be confident of the structural integrity of their wheelchair. Failure of any component is more than an inconvenience for the wheelchair users—it is the limitation of their mobility and can be life-threatening.

Tests included in the standards protocol include the curb drop and double drum. In the curb drop, the wheelchair and a 70-kg (150 lb) test dummy are lifted 5 cm and dropped to the ground. In the double-drum test, the wheelchair and test dummy are placed on two independent rollers (rear wheels on one roller and the front on the other). Each roller has two 1 cm high by 2 cm wide slats that simulate door thresholds. The standards require that the chair survives 200,000 cycles on the double drum and 6,666 drops.

A study by Fitzgerald et al. (53) compares the results of ISO standards testing on three classifications of manual wheelchairs. The classes followed Medicare definitions of K0001, depot or hospital-type (54); K0004 lightweight (55); and K0005, ultralight (56). Using ISO equivalent number of testing cycles, curb-drop and double-drum tests were expressed as a single variable, and Kaplan-Meier survival curves were determined. The fatigue life of ultralight wheelchairs was significantly greater than both the lightweight or hospital-type wheelchairs. Because ISO testing is based on a 5-year life cycle, it was concluded that lightweight and hospital-type wheelchairs might not last for the typical 3- to 5-year period expected by health insurers. A better investment for an individual patient was shown to be the ultralight, despite its initial high cost. This analysis did not take into account the other advantages of ultralight wheelchairs described in this chapter. Similar testing is being done on power wheelchairs. In general, similar to manual wheelchairs, results indicate that higher quality power wheelchairs will be less costly over the lifespan of the chairs (57).

## SECONDARY INJURY/ACCIDENTS

Unfortunately, wheelchair users are at risk for other injuries as a direct result of their wheelchair use (58). In 2003, over 100,000 injuries were treated in the emergency department. Of individuals treated, 68.9% were more than 65 years old and 65.0% were female. The highest percentage of injuries reported were fractures, contusions, and lacerations, and the leading cause of injury was from tips and falls (65% of injuries). Another important area of concern is that most wheelchairs are not crashworthy for use as seats in motor vehicles, as their seat belts and other seating components are not designed to withstand the forces occurring in motor vehicle accidents. Additional seat belts and tie downs must be used to individually hold both the patient and the wheelchair secure (59). Clinicians should be aware of this and discuss transportation directly with the patient. Additional information on the latest development of wheelchair transportation safety is available at [www.ercwts.pitt.edu](http://www.ercwts.pitt.edu).

Possibly the most important area of concern for manual wheelchair users are repetitive strain injuries of the upper extremities. These injuries are so significant that some researchers have gone so far as to say that damage to the upper limbs may be functionally and economically equivalent to a spinal cord injury of a higher neurologic level (60). The two most common areas of injury are the shoulder, with rotator cuff disease (61) and degenerative arthritis (62), and the wrist, in the form of carpal tunnel syndrome (63,64). These studies have found injury rates as high as 70%. Studies have found a direct link between manual wheelchair propulsion and injury to both the shoulder and wrist (21). Clinicians must be aware that an appropriately prescribed and setup wheelchair, which is propelled in an appropriate manner, can reduce the risk of injury. In addition, for some individuals, it may be appropriate

to discuss power-assisted or power wheelchairs as a means for preserving the upper limb for activities such as transfers. As mentioned earlier, the CPG for preservation of upper limb function specifically details the proper manual wheelchair setup and propulsion techniques to prevent repetitive strain injuries (16).

## FUNDING/INSURANCE

For many individuals, funding can present a major limitation to the type and quality of the wheelchair they can receive through their health insurance. It is tempting as a practitioner to determine the wheelchair that insurance will cover and then work from this limitation. This path can be poor for the patient and in the long term will not lead to changes in policy. Therefore, it is important that the clinician working with the patient determines the optimal mobility device. After making this determination, the team can then assess what is the best way to convince insurance that the device is medically necessary and should be covered.

Having stated this, it is helpful to know current policies and their impact on patients. The section below is focused on the United States, but policies differ markedly from one country to another. In the United States, wheelchairs and seating systems are covered in whole or part by health insurance plans, including Medicare Part B, state Medicaid programs, commercial insurance, and managed care plans, unless the policy stipulates no durable medical equipment coverage. Other funding sources also exist. If the device is needed for work-related activities, state vocational rehabilitation programs can be utilized. In addition, the Veteran's Administration for veterans with both service- and non-service-related disabilities can be a very valuable funding source.

Medicare has made significant changes to coverage policies for mobility assistive equipment (MAE, a new term they use to include canes, crutches, walkers, manual wheelchairs, scooters, and power wheelchairs) over the past several years. It is becoming increasingly difficult to get the appropriate equipment for a patient covered. Medicare funding policy for MAE is important to understand and follow, as equipment can be denied if the practitioner's documentation does not reflect what is being requested in the policy. Medicare policy is also generally adopted by most other funding sources including State Medicaid programs and private health insurance.

The new Medicare policy approaches the need for MAE from a more functional perspective and uses a new term known as mobility-related activities of daily living (MRADLs, meaning how mobility impacts a person's ability to participate in ADLs). In order to qualify for any MAE, a person has to have an impairment in "one or more" MRADL in the "home." The "in the home" language does, however, continue to be a restriction meaning that a manual wheelchair, scooter, or power wheelchair will not be covered if it is "only" to perform MRADLs outside the home. Medicare defines a mobility limitation as one that

- Prevents the patient from accomplishing an MRADL entirely (i.e., independence), or
- The patient is at reasonably determined heightened risk of morbidity or mortality secondary to the attempts to perform an MRADL (i.e., safety); or
- The patient is unable to complete the MRADL within a reasonable time frame (i.e., quality).

Although these coverage policies are based more on functional necessity and then good practice, requirements for documentation in the medical record are very specific and must be furnished to the company that supplies the equipment as they need to keep records on file in the event of an audit. Failure to provide the necessary documentation to the supplier will result in the supplier refusing to dispense the equipment. Physicians are also not permitted to complete forms provided by suppliers or manufacturers as a substitute for what is documented in the medical record. Medicare policy states that the medical record can include (but is not limited to) the items listed in Table 59-2. The policy also recognizes and encourages physicians to refer patients with mobility limitations to an occupational or physical therapist for assessment in identifying the appropriate MAE intervention and to provide necessary documentation.

The qualifying criteria for the various types of wheeled mobility devices are as follows:

*The patient has limited ability to ambulate even with the use of a cane, crutch, or walker.* For this, it is usually sufficient to explain that an individual can only ambulate short distances or is unsafe ambulating. Placing these limitations in the context of his or her current living situation and usual activities can help persuade payers of the need.

*Lightweight and ultralightweight wheelchairs.* To qualify for either of these wheelchairs, it is necessary to document that the person is unable to propel a lower-cost alternative standard wheelchair or use a cane or walker in an effective manner. It also helps document the person's lifestyle situation and how the wheelchair will facilitate his or her ability to engage in activities.

*Power wheelchairs and power-operated vehicles.* Powered mobility devices including power wheelchairs and power-operated vehicles (POVs) or scooters have been recategorized by CMS in 2006.

To qualify for a power wheelchair or POV (or scooter), one must document that the person cannot effectively propel any type of manual wheelchair. For individuals with upper-extremity paralysis, it is obvious that they cannot propel a manual chair. However, many other individuals can require a power wheelchair. People with upper-extremity pain that limits propulsion meet this criterion, because pain and risk of aggravating injury may make them incapable of propelling a manual chair. This is also true for individuals with cardiopulmonary disease or obesity. Both of these conditions make functional manual wheelchair propulsion difficult and, in some cases, impossible. These deficits and risks should be documented and explained in the LMN.

Power wheelchairs are categorized into five groups. Group 1 power wheelchairs can only accommodate people up to a weight of 136 kg (300 lb) and cannot accommodate any seat

functions such as tilt-in-space or a seat elevator. They are also not well suited to negotiate on even surfaces or thresholds more than 20 mm in height. Group 2 power wheelchairs can accommodate multiple weight capacities up to 272 kg (600 lb); however, are only designed to accommodate a single power seat function such as a seat elevator or tilt-in-space. Group 3 power wheelchairs can handle multiple weight capacities up to 272 kg (600 lb) and multiple seat functions including a vent tray and alternative controls. Group 3 power wheelchairs require a person to have a neuromuscular, myopathy, or congenital orthopedic anomaly. Group 4 power wheelchairs are similar to Groups 2 and 3 power wheelchairs; however, have features that are inherent to outdoor mobility such as larger motors and a suspension and therefore are not covered by Medicare and many other payer sources. Group 5 power wheelchairs are classified as pediatric products.

Scooters are only covered when a patient resides in a home where there is sufficient maneuvering space to operate a scooter, the patient can safely transfer in and out of a scooter, a scooter seating system will address the patient's postural needs, and the patient has sufficient upper extremity function to operate the scooter steering mechanism. Scooters are broken down into two groups. Group 1 POVs can handle multiple weight capacities and are generally designed to negotiate most level indoor and outdoor surfaces. Group 2 POVs have designed features such as larger motors and suspensions that are inherent to outdoor mobility only and therefore not covered by Medicare and many other health insurance plans.

Medicare requires that any Group 2 power wheelchair with a single power seat function, any Groups 3 or 4 power wheelchairs, or a PAPA be provided by a company that employs a RESNA certified ATS. The beneficiary receiving the equipment must also be evaluated by a qualified medical practitioner (such as an occupational or physical therapists) with experience and knowledge in complex wheelchair seating and mobility equipment. As stated early, Medicare also requires that the supplier of wheeled MAE ensures that the patient's home and environment are suitable for the MAE and that there is sufficient maneuvering space to operate the device.

## SUMMARY

As can be seen from the text, the prescription of wheelchairs is a complex and time-consuming task. Many parties need to be involved, and technology is constantly changing. In an ideal world, all wheelchairs would be prescribed using all the members of the team described earlier in this chapter, and clinicians would be reimbursed at a level that allowed for appropriate evaluation and training. Unfortunately, wheelchair clinics are costly to run; therefore, the team approach described may not be possible in many settings. It is essential that the physician signing the prescription understands the equipment well enough to explain the choices made as well as the trade-offs involved, limitations, and safety issues. Most importantly, the consumer should be able to make informed choices.

A clinician practicing without a clinic can still provide good care. The best approach is to find a therapist in the rehabilitation team who has an interest in wheelchairs. If possible, the therapist should attend meetings such as RESNA ([www.resna.org](http://www.resna.org)), the International Seating Symposium ([www.iss.pitt.edu](http://www.iss.pitt.edu)), or Medtrade ([www.medtrade.com](http://www.medtrade.com)) to learn about new technology. In addition, the therapist should consider taking the ATP examination for certification. This can be sold to the hospital as a value-added service that their institution has and others do not. The other key team member then becomes the dealer. The doctor and therapist team should request (or require) that the dealer become a CRTS. You can also ask the dealer to support the team by having equipment available for trials and by visiting the patient's house. This team can be very effective at wheelchair delivery and can improve the function and quality of life of their patients.

## FUTURE

New and exciting products are placed on the market each day. As mobility products improve, the line between needing the device because of a disability and wanting the device because it enhances mobility can become blurred. Mainstream use of assistive devices is a great thing for wheelchair users as it expands the market and lowers costs. In addition, it blurs the line between disability and normal function. In the future, it would not be uncommon for everyone to have a personal mobility device, such as Segway (65), and the only difference between individuals with disabilities and individuals without impairments is that individuals with disabilities always use their vehicle. With these advances it will be important for health care professionals to continue to lobby on behalf of their patients to increase funding for wheelchairs so that function dictates the prescription.

*Note:* Michael Boninger and Rory Cooper are coinventors on the Natural-Fit hand rim. As such they receive a royalty from the University of Pittsburgh related to its sales. In addition, Three Rivers Holdings is owned and operated by Dr. Boninger's brothers. However, neither Dr. Boninger nor Dr. Cooper has ownership in the company and neither has been or are currently paid consultants.

# Complementary and Alternative Medicine

The practice of physical medicine and rehabilitation (PM&R) is inherently a holistic discipline which focuses on the patient as a whole human being, functioning on physical, emotional, mental, social, and spiritual levels simultaneously. PM&R is a leader in integrating the concepts of holism and a diverse spectrum of therapeutic modalities into the conventional medical paradigm. PM&R and complementary and alternative medicine (CAM) share several core principles, including patient-centered care, the concept that the wisdom of the team is greater than the sum of its parts, and clinician-patient partnership. These ideas are now more commonly being adopted in other areas of medicine. Because of the similarities between the theoretical underpinnings of PM&R and of the philosophies associated with CAM modalities, CAM fits easily into the rehabilitation model. According to the National Health Information Survey (NHIS) conducted in 2007, 83 million adults spent \$33.9 billion out of pocket on CAM, and CAM costs are 11.2% of total out-of-pocket expenditures on health care. American adults are most likely to use CAM for musculoskeletal problems such as back, neck, or joint pain (1).

After World War II, the distinctive field of PM&R evolved in response to the fact that mainstream medicine was not providing adequate care and treatment for patients who had sustained injuries to the musculoskeletal and central nervous systems. In his pioneering book, *The Knife Is Not Enough*, Dr. Henry H. Kessler clearly espoused the need for what are today being called “complementary and alternative” therapies (2). He included not only physical and dietary interventions in his multidisciplinary approach, but he also recognized the important role that spirituality played in healing. This approach has marked PM&R with more openness to CAM than other specialties.

The NIH National Center for Complementary and Alternative Medicine (NCCAM) defines Complementary medicine as an approach to medical care that is used together with conventional medicine. Integrative medicine combines treatments from conventional medicine and CAM for which there is evidence of safety and effectiveness. Alternative medicine is an older term denoting the substitution of unconventional therapies for conventional modalities and is no longer current.

Because of the broad range of therapies within the realm of CAM, this chapter focuses primarily on those therapies that are currently applied in common rehabilitation conditions and settings. The goals of this chapter are to provide

(a) a brief introduction to the major CAM therapies that may be employed by physiatrists and used by patients and (b) a theoretical and research basis and where appropriate, clinical strategies for use of CAM therapies in the PM&R setting.

The evidence base for many CAM therapies ranges from inadequate (energy therapies) to more robust (acupuncture). This chapter is written as a descriptive and practical guide for the physiatrist with literature cited for further reading.

Table 79-1 presents the classification system utilized by the NCCAM to categorize CAM therapies. This chapter uses this system for organizing the various complementary and alternative techniques applicable to the rehabilitation process.

## WHOLE MEDICAL SYSTEMS

The NIH NCCAM describes whole medical systems as approaches to care that are built upon complete systems of theory and practice that have evolved independently of the conventional medical approach used in North America and Europe.

Examples of whole medical systems that have developed in Western cultures include homeopathic and naturopathic medicine. Examples of systems that have developed in non-Western cultures include Ayurveda and traditional oriental medicine.

Each of these approaches has relevance to PM&R, but the area within the whole medical systems category that currently plays the biggest role in the field of PM&R is Oriental Medicine.

## Oriental Medicine

Oriental medicine is over 3,000 years old and is based on the theory that there is a vital life force (qi) that supports physiologic functioning. Qi is concentrated in multiple pathways or channels called meridians that run longitudinally throughout the body. Health is the state in which qi is flowing abundantly and harmoniously, and illness is believed to result from an improper amount distribution or imbalance of this energy, which then precipitates physiologic change (3). Acupuncture is the insertion of thin, noncutting needles into specific acupuncture points along the meridians in order to correct aberrant energy flow. Of all modalities under the heading of Whole Medical systems, acupuncture is the most widely used in PM&R and is discussed in detail. T'ai Chi, a movement

**TABLE 79.1 Complementary and Alternative Techniques**

Categories of Complementary and Alternative Medicine	Examples
Whole medical systems	
Traditional indigenous systems	Ayurvedic medicine, traditional Chinese medicine
Unconventional Western systems	Homeopathy, naturopathy
Mind-body interventions	
Mind-centered methods	Meditation, hypnosis, biofeedback, imagery, support groups, music therapy, art therapy
Body/movement methods	Yoga, T'ai Chi, Feldenkrais method, Alexander technique, Pilates method, body-mind centering
Biologically based therapies	
Herbs, phytotherapy, supplements, diet therapy	Botanicals such as ginger, curcumin, bromelain
Vitamins and supplements	CoQ10, glucosamine/chondroitin, fish oil
Manipulative and body-based methods	Osteopathy, chiropractic, Swedish-based methods, Shiatsu, reflexology, craniosacral therapy, polarity therapy, Rolfing/structural integration, Trager therapy
Energy therapies	
Biofield therapies	Prayer, TT, qigong, polarity, Jin Shin Jyutsu, Reiki
Bioelectromagnetic-based therapies	Therapeutic use of electrical and magnetic stimulation

therapy, and qigong, an energy therapy, are all based on this concept and are discussed in separate sections.

## Acupuncture

Acupuncture has numerous applications in PM&R. It is utilized for both acute and chronic musculoskeletal and neurologic problems. Needles are placed both locally, near the anatomic location of the problem, as well as in other areas of the body. A typical acupuncture session lasts 30 to 60 minutes including examination and needle insertion. The number of sessions required depends on the intensity and chronicity of a condition as well as the age and general health of the patient. For an acute back spasm in a young and otherwise healthy individual, one to two sessions may be sufficient. For long-standing pain in lumbar spinal stenosis or motor recovery in hemiplegia secondary to cerebrovascular accident (CVA) in an older individual, up to 20 or more closely spaced sessions followed by less frequent maintenance may be required to achieve optimum results.

Recent research has begun to highlight promising avenues of exploration regarding the physiologic nature of the acupuncture channels and the points themselves (4). Histologic studies have suggested that some 80% of acupuncture points consist of a characteristic subcutaneous column of loose connective tissue, with a looped core bundle of neurovascular and lymphatic vessels that may help propagate the influence of superficial needle inputs to deeper structures (5). Decreased electrical resistance and increased capacitance have been reported between acupuncture points sharing energy channels (6). Additionally, nuclear medicine studies have shown that subcutaneous injection of technetium-99m into the low-resistance acupoints of humans and dogs results in a rapid migration of the radioactive tracer along the associated meridians; this movement is distinct from the trajectory of blood vessels, lymphatics, and

peripheral nerves, and is not observed with nonacupuncture points (7,8). More recently, similar results using gadolinium injections and MRI have been reported in humans (9). There is substantial overlap in the locations and properties of myofascial trigger points, which react to needling with a local twitch response and predictable pain radiation patterns, and acupuncture points, which react to needling with a local ache (called “*de qi*”) and radiation of this sensation along the associated acupuncture channels (10). However, as acupoints are not always tender to palpation and are often used for other indications aside from local pain, debate exists about whether trigger points may merely represent a smaller subset of acupuncture points called “*a shi*” points (11–13).

Anatomic studies *in vivo* and postmortem section in the upper arm have revealed that more than 80% of acupuncture points and 50% of meridians correspond to intermuscular and intramuscular connective tissue cleavage planes (14). Microscopic images show that the tissue resistance “needle grasp” effect (a sensation of resistance felt by the practitioner when the acupuncture needle has been advanced to its desired depth in some acupoints) that is clinically recognized upon twisting an inserted needle actually corresponds to the winding of collagen fibers and fibroblasts in the connective tissue around the surface of that rotated needle (14–17). Needle grasp of acupoints may thus propagate a mechanical stretch to the deeper fascial matrix, which ultimately invests structures such as the peritoneum of the viscera, the pleura, the perineurium, and the meninges (14). Mechanotransduction of this stretch converts into a potentially gene transcription–altering intracellular signal by deforming the cytoskeletons of fibroblasts and directly influencing actin and microtubule remodeling, as shown in a murine model (18,19). Related studies have demonstrated that cyclical stretching of fibroblasts in this fashion decreases TGF- $\beta$ 1 production and type 1 procollagen

deposition (both factors normally promote fibrosis), which begins to suggest a common hypothesis explaining the therapeutic benefits of fascial stretching modalities such as physical therapy, massage, osteopathy, Rolfing, yoga, and acupuncture (20,21).

It has long been known that acupuncture stimulation acts on the autonomic nervous system and causes the release of endogenous endorphins, enkephalins, monoamines, and other neurotransmitters that play central roles in acupuncture analgesia (5). More recently, neuroimaging has revealed a glimpse into the CNS networks that are manipulated via acupuncture stimulation (22). Studies using functional MR have shown that needling certain acupuncture points activates areas of the somatosensory cortex that do not correspond anatomically, but do correspond functionally under classical East Asian medical theory, although these data are still under debate (23–30). Major acupuncture points traditionally needled for pain management have been shown on fMRI to modulate activity in areas such as the hypothalamus, prefrontal cortex, insula, limbic system, and periaqueductal gray matter (31–34), which may help attenuate both the sensory and the emotional perception of pain and coordinate an autonomic response (22). Even after acupuncture stimulation is terminated, changes persist in the central connections among the limbic areas for pain, affect, and memory (35). These results may have significant implications for the rehabilitation of other disorders involving cerebral cortical remodeling, such as stroke, phantom limb pain, and neurodegenerative syndromes.

Controlled clinical trials have shown acupuncture to be effective for osteoarthritis (36), neurogenic pain following spinal cord injury (SCI) (37), neurogenic bladder (38), lateral epicondylitis, addiction, headache, tennis elbow, fibromyalgia, myofascial pain, low back pain, and carpal tunnel syndrome (39). Meta-analyses have reported that acupuncture has shown efficacy in the treatment of tension headache (40) in migraine prophylaxis (41), and as an adjunct to low back pain rehabilitation (42), but that further study is required to make conclusive statements regarding benefit or lack thereof in stroke rehabilitation (43–45) and rheumatoid arthritis (46). In practice, acupuncture is used to treat multiple conditions including osteoarthritis, lumbar spinal stenosis, tension headaches, muscle and ligament sprains, carpal tunnel syndrome, lateral epicondylitis, motor recovery after stroke, neurogenic pain, bowel and bladder dysfunction following SCI, early peripheral neuropathy, and migraine headaches among other conditions. Acupressure is a technique based on the concept of meridians and acupoints, but instead of needle insertion, pressure is applied to the acupoint. In practice, acupressure may be thought of as a weaker form of acupuncture. Patients may be given acupressure points as a part of their home exercise program to enhance the rehabilitation process.

Acupuncture has, generally, been found to be safe, and the rare complications can be minimized by using licensed practitioners (47). One study indicated that blood pressure should be monitored in SCI patient (48). Overall, acupuncture shows promise as a useful treatment modality in the PM&R setting.

## Homeopathy

Homeopathy is the system of diagnosis and treatment developed by Samuel Hahnemann, MD, a German physician who viewed the symptoms of an illness as a reflection of the body's attempts to regain homeostasis. He postulated that if we could properly interpret these symptoms, we could then direct the body's own homeostatic mechanisms toward healing illness. Hahnemann reported that when a small test dose of a biological substance is given to a healthy person, it elicits a predictable array of signs and symptoms. Hundreds of substances have been tested in this manner (this is referred to as a "proving") and logged in the Homeopathic Materia Medica. Homeopathic theory states that a dilute amount of this substance will help to direct the body's innate healing mechanisms toward balance. When a patient becomes ill, symptoms are recorded and closely matched to the material that causes similar symptoms in a healthy person. The homeopath combines this information with past medical and social history, and examination in order to prescribe a homeopathic remedy. Prescription of remedies in homeopathy is highly individualized, since the mental-emotional pattern, general level of health, and particular physical attributes of the patient are all taken into consideration. The underlying theory is that the remedy will help to steer the body back to homeostasis.

Many medical doctors in the United States used homeopathy in the early 1900s, and there were 16 homeopathic medical schools in the United States at the beginning of the 20th century. Since then its popularity declined until recently and in 1997, 3.4 million visits to homeopathic providers were reported in the United States (49,50). Research in homeopathy using current double-blind placebo-controlled methods presents considerable difficulty. Two patients with the same allopathic diagnosis may have two completely different symptom complexes when the patient is examined from a homeopathic point of view. The result is that two different homeopathic remedies may be prescribed for two patients with the same allopathic diagnosis. Nonetheless, it has shown to be useful in the treatment of mild TBI (51) and some musculoskeletal problems (52–54). A meta-analysis of four trials on osteoarthritis concluded that although the clinical evidence appears promising, the small number of randomized clinical trials conducted to date, although favoring homeopathic treatment, did not allow a firm conclusion as to the effectiveness of homeopathic remedies in the treatment of patients with osteoarthritis (55).

## Ayurveda

The indigenous healing system native to India, Ayurveda translates as the "science of life." The basic principles of Ayurveda include the interconvertability of energy and matter and the interconnectedness of all life (56). Like the field of PM&R, Ayurveda teaches that disease and healing occur on all levels: physical, emotional, mental, and spiritual. Everything in the cosmos is believed to be made up of varying proportions of the five elements—earth, air, water, fire, and space. According to Ayurveda, these elements also occur in people in varying

proportions that are grouped into types functionally classified as *doshas*. These proportions make up the individual's *prakriti*, or individual constitution, and determine the mental and physical makeup of each individual. Illness is thought to occur when there is an imbalance in the *doshas*. Each dosha has corresponding symptoms and illnesses that occur during imbalance. Treatments are individualized by constitutional type and include herbs, yoga postures, diet, pranayama or breathing techniques, purification techniques, meditation, and mantras (25).

Ayurveda is not well integrated into the PM&R setting at this time. However, one tool used by Ayurvedic practitioners, yoga, is discussed in separate sections below.

### Naturopathy

Naturopathy is a system that stresses health maintenance and disease prevention through patient education and acceptance of responsibility for one's own health. Underlying the various treatments in naturopathic medicine is the belief in the healing power of nature, and the innate intelligence of the body. Naturopathic physicians are trained in the medical sciences as well as combinations of disciplines such as herbology, nutrition, homeopathy, or acupuncture. A naturopathic doctor holds the degree ND and has 4 years of training followed by an internship. Naturopathic physicians are licensed in some states and Canadian provinces, and scope of practice for some includes limited drug prescription.

## MIND-BODY INTERVENTIONS

The basic premise of mind-body interventions is that the mind and body are not dualistically distinct entities but exist on a continuum. Thus, thoughts and emotions influence the body, and physical processes have an impact on the mental, emotional, and spiritual state. Mind-body interventions may be separated into either a mental or physical process that influences this mind-body continuum. "Mind"-based techniques including visual imagery, art and music therapy, biofeedback, hypnosis, meditation, and prayer are designed to act through the mind to alter its state and thus physical conditions including muscle tension, endorphin levels, and pain. Body-based techniques use the body as a vehicle and act to increase strength, flexibility, and body awareness and in so doing, impact upon mental/psychological/spiritual states such as level of mental focus, anxiety, or compassion for self and others. Modern day usage and supporting evidence are listed for mind-body techniques separately below.

### Hypnotherapy

Hypnotherapy works at the level of the subconscious mind to assist patients in making positive behavioral changes and to decrease symptoms. A clinical hypnotherapist makes use of therapeutic suggestion while an individual is in a highly relaxed and altered state of awareness. Hypnotherapy is used to improve self-esteem, improve mood, increase feelings of self-efficacy, and control and decrease negative behaviors and fears that interfere

with recovery. In case reports of patients treated with hypnosis following a stroke, observations were made of increased movement in hemiplegic limbs and improved ambulation (57–59) as well as the return of normal speech (57,59). Hypnosis was used in the treatment of headache or vertigo following brain injury in a series of 155 patients, with half reporting resolution of symptoms and another 20% experienced significant symptom reduction (60). In the area of musculoskeletal rehabilitation, hypnosis, when used, is largely for pain control. One NIH consensus review panel and one meta-analysis suggest that hypnotherapy may be a useful adjunct to the treatment of chronic low back pain and other neuromusculoskeletal conditions (61,62). Positron emission technology (PET) scanning reveals that the hypnotic state is related to the activation of a widespread set of cortical areas involving occipital, parietal, precentral, premotor, and ventrolateral prefrontal and anterior cingulate cortices (63).

### Meditation

In some form, meditation has long been used in many cultures, both Eastern and Western. Originally, it was tied to religious practices and was performed with spiritual goals of enlightenment. Modern forms of meditation have separated the techniques from their religious contexts, and the goals for which meditation is used have become more concrete, for example, decreased anxiety and improved health. While there are many forms of meditation, most are intended to create a state of physical and mental relaxation. Most forms of meditation involve sitting or lying quietly while focusing on one or two stimuli, such as breathing patterns, a word, or an image.

The most robust finding on the impact of meditation is the success of meditation for reducing hypertension (64–67). Research evidence for the effectiveness of meditation in the rehabilitation process is limited to anecdotal reports (68).

Meditation has been shown to improve cognitive functioning in college students and elderly adults who have no history of head injury (69,70). For pain and musculoskeletal conditions, studies indicate that the practice of meditation as part of a comprehensive treatment program can improve self-management of chronic pain (71), fibromyalgia symptoms (72) and perception of pain in arthritis (73). Although multiple studies have been performed on the effect of meditation on various conditions, for the most part, methodological quality has not been sufficient to allow conclusive statements on effectiveness (74).

### Mind-Body Movement Therapies

Described here are six of the more popular therapeutic movement modalities in use today: yoga, T'ai Chi, the Alexander technique, the Feldenkrais method, Pilates, and body-mind centering (BMC). These techniques are similar in that they aim to improve a patient's kinesthetic ability, coordination of motion and breathing, and ease, control, and joy in everyday movement. All may be useful for a wide spectrum of patients from severely physically challenged to high-performance athletes.

Yoga and T'ai Chi, are frequently referred to as "mind-body" techniques, because they actively seek to balance both

the physical and nonphysical aspects of the person. Both are meditative in nature and are part of a larger philosophy or way of life. Each is derived from a broader system of health with an underlying model differing from those of the West. The other five techniques described were developed in the 20th century. All of the techniques take a less focal and more global approach to rehabilitation of specific conditions based on the rationale that the whole body is involved in all movement. A summary of CAM movement therapies and indications is listed in Table 79-2.

### Yoga

Yoga is an ancient Indian art first brought to this country in the mid-1800s. In Sanskrit, the word “*yoga*” means “union” (with the Divine), and is a way of life involving a number of different spiritual practices and encompasses ethical conduct, social responsibility, nutrition, and physical health practices. The branch of yoga that is best known in the West is *hatha yoga*, and is often simply referred to as “yoga.” Originally intended to prepare the body for Divine experience, it is practiced in this country for the achievement of physical strength, flexibility, and relaxation through postures known as *asanas* (*a-sa-nas*). *Pranayama* (*pra-na-ya-ma*), or breathing techniques, and meditation are also often practiced along with hatha yoga. The

many forms of yoga practiced in the United States are diverse in terms of focus, strenuousness, and applications. A few of the forms most relevant to PM&R are described in Table 79-2.

Yoga has been extensively studied both in India and the West, with thousands of studies reporting positive health effects, including lowering of blood pressure (75), and decreased cholesterol levels (76). Yoga has been applied to programs for rheumatoid arthritis (77), osteoarthritis (78), chronic back pain (79), cardiac rehabilitation (80), carpal tunnel syndrome (78), and improved athletic performance (81). Yoga is increasingly being integrated into the office and inpatient settings by instructors who are experienced in teaching rehabilitation patients (82). Individual sessions and classes are a convenient way to transition from physical therapy supervision to a home-based program (83).

### T'ai Chi

T'ai Chi is a form of postures and movements that dates back to 17th century China. T'ai Chi is made up of a series of flowing contrasting movements, with constant weight shifting from one leg to another, changing of direction, and moving the limbs in space. Specific postures are linked together with the focus on achieving balanced and graceful movement. Since it is a slow, rhythmic and weight-bearing exercise, participants

**TABLE 79.2** Movement Therapies

Technique	Focus	Indications, Precautions, Considerations
Anusara yoga (Sanskrit for “flowing with grace”)	Alignment, smooth flow of poses, use of yoga to maintain health	General health, balanced combination of alignment, posture flow and heart-centered approach; rigorous certification process
Kripalu yoga (Sanskrit for “compassion”)	Gentle movement, strength and flexibility, awareness and care of the body, release of emotions	Deconditioning, neck and back pain, ROM deficits, fibromyalgia, initial rehabilitation phase of recovery from illness esp. post-cardiac, postsurgical, increasing general strength and flexibility; broad-based certification process
Iyengar yoga	Alignment, correct execution of poses, use of yoga to correct physical health problems	Back and neck pain, scoliosis, sports rehabilitation; significant use of props and modifications for physical limitations; rigorous certification process
Viniyoga	Tailoring practice to the individual, therapeutic linking of breath with movement	Severe deconditioning, general conditioning, neck and back pain
Ashtanga yoga, Bikram yoga	Strength building	Athletic and mental conditioning; not to be used in serious injury, deconditioning, or rehabilitation
T'ai Chi	Balance, flexibility, stress reduction, body awareness	Fall-prone patients, peripheral neuropathy neck and back pain, general deconditioning. Requires ability to stand; may be modified to patient needs
Feldenkrais	Exploration and choice of useful movement; application to functional tasks	Neurological disorders, orthopedic rehab, neck and back pain; rehabilitation of dance and musician injuries
Alexander technique	Posture and alignment, release of maladaptive movement habits, low back and neck pain	Neck injuries, scoliosis, low back pain, neck pain, rehabilitation of dancer and musician injuries and any activity in which proper posture is important
Pilates	Core strengthening, balanced strengthening, ease of movement	Athletic rehabilitation, general strengthening, neck and back pain, postural awareness; avoid with moderate to severe injury unless practitioner has rehab experience
Body-mind centering	Awareness through touch, movement, and intention	Developmental delay, CP, autism, stroke, TBI, SCI, neck and back pain

are able to improve balance, coordination, concentration, and relieve stress in a safe manner. Randomized trials report that benefits of T'ai Chi include improved cardiorespiratory function, improved strength and balance, decreased falls in the elderly (84–87), and improved psychological parameters (88). T'ai Chi has been modified for the elderly (T'ai Chi Chih), and the arthritis population and instructors are now certified by the Arthritis Foundation.

### Movement Awareness Techniques

Movement awareness techniques focus less on strengthening isolated muscles and more on ease and comfort in functional movement. Each one promotes body awareness and balance and may be taught in one-on-one or in group format. The Alexander technique was developed by FM Alexander, a Shakesperian actor, in his attempts to heal his own recurrent loss of voice. Alexander found that his voice improved when he decreased his cervical tension. His technique attempts to improve posture and movement by focusing on developing a balance between the head and neck in static and dynamic situations, as well as proper breathing (89). Most sessions are one-on-one, with the practitioner directing the student verbally and with light touch into postures that will help him or her to experience the state of being in proper alignment. Alexander practitioners are consulted for any patient with postural difficulties or chronic and occupational back and neck pain. Clinical reports include effectiveness in increasing respiratory capacity (90) in Parkinson's (91) or for improved performance in athletics and the performing arts.

The Feldenkrais method is a movement therapy that capitalizes on the ability of the human nervous system to develop new engrams or movement patterns. It was developed by Moshe Feldenkrais, PhD, a physicist and judo black belt who studied Alexander technique, yoga, psychology, and other disciplines and applied them to injury rehabilitation. This method teaches the patient to break down and examine functional movement habits and to choose new patterns based on their usefulness and efficiency. The technique helps patients to learn to use efficient and pain-free movement. Feldenkrais sessions are conducted in two formats. Awareness through movement is a verbally directed group lesson in which movements are gentle and slow, within comfort range. Lessons are based on a function (getting up from a chair, rolling from supine to prone). The second variation, Functional Integration, is a one-on-one, hands-on technique in which the practitioner gently guides the student through various movement sequences. Feldenkrais has been used with various conditions, including cerebral palsy, hemiplegia, and multiple sclerosis. There are reports of the successful use of the Feldenkrais method in multiple sclerosis (92), orthopedic injuries (93), Parkinson's disease (94), and neck and low back pain (95,96) and evidence that it is cost effective in the management of chronic pain (97). A review of the numerous studies on Feldenkrais in rehabilitation concluded that with a great number of positive case reports, further research with rigorous methodology is warranted (98).

The Pilates method was developed by Joseph Pilates during and after World War I and combines the experiences he gained as a result of his contact with dancers, athletes, and disabled soldiers. The technique is now used by many high-level athletes and dancers as well as those undergoing rehabilitation, especially for musculoskeletal conditions. This popular technique is characterized by use of proper body mechanics, stabilization of the shoulder and pelvic girdles, and coordinated breathing to promote strengthening with minimal increase in bulk. A typical rehabilitation program using a Pilates-based approach may begin not by focusing on the area that is injured but by teaching exercises to enhance awareness that the body works as a whole and that the injured part is weak link in the entire kinetic chain (99). Clinical reports of the use of Pilates-based protocols are in the area of sports training and rehabilitation (100,101).

Bonnie Bainbridge-Cohen developed BMC, a unique approach to movement analysis and reeducation (102). Cohen drew on her training in occupational therapy, and Bobath's neurodevelopmental therapy, dance therapy, bodywork, martial arts, voice, and yoga.

The primary goal of BMC is the integration of body and mind, and the development of an ability to sense this connectedness. BMC teaches students to tune into the body and feel at the tissue and cellular levels. BMC holds that the body's tissues have the ability to respond to messages given to them (102). Thus, body tissues can be affected by the practitioner's hands as well as the patient's actions, thoughts, and intentions. The result is the modulation of pain and restrictions preventing optimal movement. BMC is used for patients affected by any neurological or musculoskeletal condition including developmental issues, stroke, SCI, TBI, and orthopedic conditions.

## BIOLOGICAL THERAPIES

Biological therapies refer to modalities which act by biochemical means to elicit a desired outcome. The category includes diet, herbal, and vitamin supplements. Biological therapies are appealing to the public because of their accessibility and perceived efficacy and safety. According to the most recent NHIS report in 2007 (103), the most common supplement used by Americans is fish oil, followed by glucosamine. Because of patient request for natural therapies, wide usage, increasing literature support, and their unique side effect profiles and interactions, physicians should be familiar with the range of biological treatments frequently used for musculoskeletal disorders.

Unlike conventional pharmacologic treatments which undergo rigorous testing for safety and efficacy and must be approved by the FDA before they are marketed, herbs and nutritional supplements are not held to the same quality standards. In 1994, Congress enacted the Dietary Supplement Health and Education Act (104) which defines "dietary supplement" as products taken by mouth which contains one or a combination of vitamins, minerals, herbs or other botanicals, amino acids,

concentrates, metabolites, constituents, or extracts. The Act makes manufacturers responsible for ensuring the safety and efficacy of their products by listing all ingredients and including a disclaimer stating that the product has not been evaluated by the FDA and “is not intended to diagnose, treat, cure, or prevent any disease” (104). Good Manufacturing Process or GMP is a set of standards voluntarily adopted by manufacturers, and the acronym GRAS, or Generally Regarded As Safe, reflects a level of safety that is agreed upon by experts. The FDA prohibits use of any food additive or supplement that is not GRAS (105).

The agents discussed here were chosen from a long list of supplements as those that have the most literature support and which are relevant to PMR conditions. The majority of herbs and supplements used in common disorders seen by PM&R professionals are used for pain management of musculoskeletal conditions and have some anti-inflammatory mechanism (see below); others have structural modification properties, still others have diverse mechanisms.

Before discussing supplements with patients, it is wise to discuss the effect of diet in a healing neuromusculoskeletal system. The importance of nutrition cannot be overemphasized. Because the Standard American Diet (SAD) contains significant amounts of precursors to proinflammatory fatty acids (saturated fat, vegetable oils, most nuts), with lesser proportions of foods that give rise to the manufacture of anti-inflammatory compounds (fruits and vegetables, omega-3-containing nuts, cold water fish), many patients ingest a diet that contributes to a high inflammatory load (106). Since most pain syndromes are associated with inflammation (107), an anti-inflammatory diet is a prudent choice for patients in pain or with healing neuromusculoskeletal systems. The basic principles of an anti-inflammatory diet include reduction of sources of arachidonic acid (mainly saturated fat), elimination of trans fats, which interfere with essential fatty acid (EFA) metabolism, optimization of omega 6 to omega 3 ratios, consumption of abundant and variety of phytochemicals from fruits and vegetables, and use of anti-inflammatory herbs and spices. Several popular guides to an anti-inflammatory diet exist (108,109). There is evidence that an anti-inflammatory diet supports the actions of anti-inflammatory supplements and decreases symptomatology in patients with systemic inflammatory conditions (110). There is an increasing number of reports of correlation between dietary imbalances and autoimmune musculoskeletal diseases (111,112), osteoporosis (113–115), and inflammatory conditions (116), and therefore opportunities for intervention. The physiatrist who makes herself/himself aware of these relationships and seeks appropriate help may help save the patient years of suffering.

One of the most discussed supplements in medicine today is the use of fish oil. Fish oil contains eicosapentaenoic acid (EPA) and docosapentaenoic (DHA), both precursors in the manufacture of anti-inflammatory compounds. EPA and DHA are necessary to the development and maintenance of healthy membranes, and deficits associated with

aberrant receptor binding capacity, cell signaling, and neural development. The use of fish oil has been well studied in the rheumatoid arthritis population, and patients tolerate high doses (4.5 g/d DHA/EPA) with no negative incidents in 3 years of follow-up (117). Approximately 2 to 3 g/d of combined DHA/EPA is considered anti-inflammatory, and patients should be started at approximately 2 g/d and titrated upward as tolerated (117). Omega 6: Omega 3 ratios can be periodically monitored.

Glucosamine, widely used for joint pain, is the supplement that has the second highest frequency of use in the United States and is in the category of structure-modifying agents. Glucosamine is made from glucose and the amino acid glutamine and is a fundamental building block for glycolipids, glycoproteins, glycosaminoglycans, and hyaluronate. It is required for production of glycosaminoglycan, a molecule used in the formation and repair of cartilage and other body tissues. The production of glucosamine slows with age.

Over 20 trials have examined the effectiveness of glucosamine with variable results (118). Some of the important variables in such trials include glucosamine preparation (glucosamine sulfate vs. glucosamine hydrochloride), dosing schedule, and outcome measures (pain, function, radiographic change). The GAIT and GUIDE trials are the two most definitive trials, and illustrate this point well. The GAIT trial used five conditions: glucosamine HCl 500 tid versus chondroitin sulfate 400 tid versus combination versus celecoxib 200 qd versus placebo  $\times$  24 weeks in a total of 1,583 patients that were stratified into mild, moderate and severe. Despite an unusually high placebo response (60%), there was a mild response in the glucosamine sulfate combination in the moderate-severe group (119). In the GUIDE trial, glucosamine sulfate 1,500 mg was superior to acetaminophen 3,000 mg in a total of 318 patients  $\times$  24 weeks (120).

In studies evaluating the pharmacokinetics of glucosamine, the serum level peaks at 10  $\mu$ m after oral ingestion, which is thought to be insufficient for clinical effect. Glucosamine may act as a carrier for sulfate. This hypothesis predicts better performance of sulfate versus nonsulfate glucosamine salts (121–123). Glucosamine may also have an anti-inflammatory effect via inhibition of the IL-1 signaling cascade and down-regulation of the catabolic effects of proinflammatory molecules present in osteoarthritic cartilage. It also inhibits production of matrix metalloproteinase-3 (MMP-3) which degrades the collagen matrix.

Two studies evaluated the effect of glucosamine sulfate (1,500 mg qd) on joint space narrowing after 3 years, and both showed an increase in joint space as compared to placebo (124,125). Furthermore, 5-year follow-up showed a 0.52 relative risk of lower limb surgery (124) and 75% reduction in knee replacement surgery (125) compared to placebo.

There has been some suggestion that glucosamine was associated with increased blood glucose levels but that has been refuted (121). No other significant side effects have been reported.

### Avocado/Soybean Unsaponifiables

A preparation of the unsaponifiable fractions of avocado and soybean is reported to repress the catabolic activities of chondrocytes and to increase proteoglycan accumulation by OA chondrocytes. Avocado/soybean unsaponifiables (ASU) have been shown to inhibit basal MMP-3 production and inflammatory cytokine production and to have a chondroprotective effect via IL-1-repression (126). Two randomized controlled trials in patients with hip and knee osteoarthritis taking ASU found a reduction in nonsteroidal anti-inflammatory drugs (NSAID) usage. *Disease modifying* effects following the administration of ASU were reported in human OA of the hip (127). Dosage is 300 mg/d, standardized to 30% phytosterols; precautions include cross-reactivity in patients with latex allergies.

### SAMe

S-adenosylmethionine (SAMe) is an amino acid precursor which is found naturally in human cells and has been used in Europe for over 25 years for the treatment of a broad range of conditions including osteoarthritis, depression, and fibromyalgia. The mechanism of action appears to be its involvement in several metabolic processes including those which synthesize proteins and detoxify substances in the liver (128). With respect to osteoarthritis, SAMe increases chondrocyte viability and function (129), likely by acting as a restorative after damage induced by TNF- $\alpha$  (129). It has been found in clinical trials to be as effective as naproxen 750 mg/d, indomethacin 150 mg/d, piroxicam 20 mg/d, and ibuprofen 1,200 mg/d (130). Dosage in such trials ranged from 400 to 1,600 mg.

### Antioxidants

While a full discussion of all antioxidants that could be of benefit during rehabilitation is not possible here, a few noteworthy associations stand out: Coenzyme Q10 (CoQ10), or ubiquinone, is manufactured in the body and is an essential contributor to mitochondrial function and is depleted by statins. CoQ10 has been shown to increase the time between the diagnosis of Parkinson's disease and the need for medication in a dose-dependent manner. Optimal dosing is 1,200 mg/d, but may be effective in lower doses if given in conjunction with other antioxidants. A 50-day course of vitamin C, when given at the time of diagnosis of wrist fractures, prevented the development of complex regional pain syndrome (CRPS) in a dose-dependent manner (131). Alpha lipoic acid is a potent antioxidant that has been used to treat painful peripheral neuropathy. Earlier trials showed mixed results, but a more recent multicenter trial using IV alpha lipoic acid trial at three doses (1,200, 600, or 100 mg ALA), 82% of the group receiving 600 mg had significant relief of symptoms at 19 days. It is not known whether oral dosing will give the same effect (132).

### Anti-Inflammatory Botanicals

Patients at times seek an opportunity to use natural anti-inflammatory and circulation enhancing supplements. Most

botanical anti-inflammatory agents act in a manner similar to NSAIDs without the same side effects. *Boswellia serrata* (frankincense) has been found to be helpful in the treatment of OA of the knee (133) and other chronic inflammatory diseases (134) and to potentiate glucosamine action (135), probably by blocking arachidonic acid to leukotriene conversion (136). Bromelain is a sulfur-containing enzyme from the pineapple plant which has been found to inhibit PGE2 and enhance PGE1 synthesis and to have separate analgesic properties. Effective dosage in studies ranges between 100 and 900 mg/d, with no significant adverse effects (137). Zingiber (ginger) inhibits COX and LOX pathways (138) and is commonly used to enhance digestion of herbal substances in Chinese Medicine. *Curcuma longa* (curcumin) is used in many pain formulae and has been investigated for effects on autoimmune disease (139); *Harpagophytum procumbens* (Devil's claw) has undergone multiple placebo-controlled trials demonstrating success with and is prescribed widely in Europe for low back pain (140); *Salix alba* (white willow bark) has been trialed successfully and is used for migraine prophylaxis and low back pain (141). All of these compounds inhibit conversion of arachidonic acid to proinflammatory compounds. These compounds are often found in combination, with less than the maximal amount of each substance, with the rationale that the sum of multiple agents will be mutually potentiating without the need for high doses of each agent.

Vitamin D is more aptly termed a hormone and has been found to be low in patients with osteoarthritis, cancer, multiple sclerosis, and associated with muscle soreness in older women (142). Recommendations are for levels to be maintained between 50 and 100 ng/mL. Dosage to achieve this is 1,000 U/d or for monitored patients, 50,000 U weekly for 8 weeks (prescription only) (143).

The leaf of the ginkgo tree has been part of the traditional Chinese pharmacopoeia for 500 years. A standardized extract of the ginkgo leaf is widely used in Asia, Germany, and France, and is increasingly being used in the United States. There are multiple active ingredients in the extract, including amino acids, flavonoids, flavonols, and steroids. Ginkgo biloba extract has been used in the treatment of symptoms associated with cardiovascular injury, traumatic brain injury, dementia, and memory impairment (144). One placebo-controlled trial found no effect of ginkgo on memory enhancement in healthy patients over 60 (145). There have been multiple trials examining the effect of ginkgo on cognition in healthy and impaired populations (146), but at this time there is no convincing evidence that it should be recommended for routine care in the enhancement of memory in healthy patients, in the prevention of stroke, or in the reduction of cognitive decline. The usual pharmacologic regimen for the treatment of cerebrovascular disease is 120 to 240 mg in divided doses (147).

The physiatrist should advise patients that "natural" does not mean "safe" and that research on supplements is in its infancy. Just as with some pharmaceutical treatments, "nutraceutical" agents designed for therapeutic benefit may

later prove to be unsafe under certain circumstances or of no benefit. It is important to make the decision to use both pharmaceuticals and supplements after balancing the patient's specific needs with data on efficacy, safety, and drug-drug and drug-supplement interactions (148).

## MANIPULATIVE AND BODY-BASED THERAPIES

Manipulative and body-based therapies are employed to improve the structure and functioning of the body by manipulation of the musculoskeletal structure. Although often considered to be “unconventional” in mainstream medicine, many forms of physical manipulation and massage have been utilized for years in PM&R and osteopathic manual medicine. Typically, massage done in the context of PM&R is based on Swedish massage. A detailed discussion of the theoretical basis and nomenclature for massage is presented in Chapter 64. Less conventional bodywork concepts and techniques are briefly reviewed below. An excellent introduction to a number of bodywork, mind-body, and energy techniques applied to the rehabilitation process can be found elsewhere (148–150).

Eastern massage styles, such as acupressure, shiatsu, and tuina, are derived from the original Chinese massage/manipulation technique known as anmo (“press and stroke”). These techniques involve hand movements familiar to Western practitioners such as pressing, stroking, kneading, and grasping, as well as others such as joint manipulation, knuckle rolling, and use of the feet and knees to tread on the client that are outside the scope of Western massage therapy. As with acupuncture, smooth and adequate flow of energy (chi) is considered the basis for good health. The most widespread use of Eastern massage techniques in the United States is by massage therapists trained in Western massage technique, integrating these additional skills into their practice. Acupressure usually takes place on a treatment table, and lubricants are not ordinarily used. Case studies report it to be effective for the treatment of headache and temporomandibular joint pain, postoperative pain, and as an adjunct to pulmonary rehabilitation (151). *Shiatsu* means “finger pressure” in Japanese. Although the term is used synonymously with acupressure, the two are distinctly different therapies. In shiatsu massage, the session is performed on the floor on a blanket or futon rather than on a table. This allows the practitioner to use various parts of his or her own body (feet, legs, or full body weight) for efficient application of pressure over points and along meridians. Passive stretching and range of motion are also a part of the session. *Tuina* (“push and pull” or “push and squeeze”) is a massage/manipulation technique encompassing a variety of hand strokes, ranging from gentle and superficial movements to techniques with vigorous articulatory maneuvers. It may be roughly equated with Western manipulative techniques. Tuina is taught in the North America as a part of Chinese bodywork training in schools of oriental medicine.

## Craniosacral Therapy

Craniosacral therapy is an osteopathic technique developed by William Sutherland DO in the early 1900s (126). It is a gentle, noninvasive manipulative technique applied to the spinal cord and cranium to correct disruptions in the craniosacral rhythmic activity. This activity is believed to be disrupted in orthopedic trauma, spinal cord and traumatic brain injury; so one of the major focuses of this technique has been this type of injury (151,152). Upledger reports success in treating chronic pain, chronic brain dysfunction, spasticity, and other conditions associated with spinal cord injury. A number of other conditions have also been treated with this technique; however, there is little formal research supporting its efficacy.

## Rolfing

Rolfing was developed in the 1950s by Ida Rolf, a chemist who approached the body as a group of units (head, shoulders, trunk, pelvis, and limbs) connected to each other by the fascial network and with gravity (149). She used this concept in her approach to help clients achieve proper vertical alignment and efficient movement. The method is characterized by the release of restrictions in the deep fascial planes in the body, allowing shortened and tense muscles to relax and lengthen. The goal is to balance and align the body in the gravitational field. The practitioner uses a series of ten 60 to 90 minute sessions, working from superficial to progressively deeper structures, each session building upon the previous one. These may be followed by additional sessions after the client has had time to incorporate the changes into daily habit. Movement education may also be used in conjunction with hands-on work. Traditionally, the Rolfing treatment consists of a series of sessions, each concentrating on specific body regions. The intensity of pressure on muscle and connective tissue that characterizes the original style used by Rolf has been refined by many subsequent practitioners of Rolfing. In the rehabilitation setting, Rolfing has been used by therapists integrating the techniques into musculoskeletal and neurological rehabilitation. A case series of patients with cerebral palsy and varying levels of motor impairment suggested that Rolfing was of benefit in improving locomotor capacity in patients with mild CP involvement (153). *Structural Integration*, developed by a student of Rolf, uses a similar approach and philosophy. Increasing recognition of the importance of the fascia in structural and metabolic health (19) gives a new appreciation for the work of Ida Rolf and her colleagues.

## Trager Psychophysical Integration

Trager therapy involves a combination of gentle, hands-on tissue technique movement, reeducation, and relaxation exercises (125). Developed by Milton Trager, MD, in the 1940s, it attempts to teach patients to move with ease and efficiency. The work consists of gentle rocking, stretching, and rolling movements intended to relax and enliven tense areas of the body. The Trager therapist attains a calm and focused state of mind in order to be in contact with the client's needs and responses. The practitioner manually communicates this light

and energetic state to the client's body so that the body may relearn a feeling of ease in movement. Tragerwork may be used for the rehabilitation of sports and musculoskeletal conditions. In a controlled trial, Trager was equal to acupuncture for relief of chronic shoulder pain in spinal cord injured patients (154). Case studies suggest its usefulness as a useful adjunct in rehabilitation of chronic obstructive pulmonary disease (155) and cerebral palsy (156).

## ENERGY THERAPIES

Energy therapies may be divided into biofield therapeutics, or the assessment and adjustment of the human energy field, and electromagnetic therapies (magnets). Biofield therapies are discussed here. Biofield healing is the most controversial of the unconventional modalities, because it postulates the existence of a subtle energy field within and around the body that cannot be measured by standard biomedical instrumentation. Although unrecognized in modern biomedical science, the existence of this subtle energy is an integral part of almost every traditional ethnic medical system, and the concept dates back thousands of years. The energy field is known as the vital life force in Western metaphysical traditions, and as *qi* or *chi* (Chinese), *ki* (Japanese), and *prana* (Sanskrit) in Eastern traditions. All of the techniques have as a basic underlying concept—the idea that illness is a result of, or at least associated with, imbalances and blockages in this energy field.

The various techniques included in this group of therapies involve a practitioner placing his/her hands on or near the physical body and either actively or passively altering the energy in the recipient's field. Although light physical touch may be involved, its purpose is to modulate the energy field, not to manipulate the skin, muscle, or other organ, and the mechanism of action is quite different from that usually proposed in manual manipulation techniques. It should be noted, however, that a number of techniques (e.g., Jin Shin Jyutsu [JSJ] and Polarity Therapy, described below) have been developed during the past few decades that combine physical manipulation with subtle energy healing. In traditional systems of medicine, such as Chinese Medicine and Ayurveda, massage and energy healing, while seen as separate techniques, are often used together. Although generally used to promote the overall health of the individual, these techniques have been used to treat specific diseases and medical conditions.

### Prayer and Spiritual Healing

Prayer is discussed here as a mental process outside the context of any particular religious system. There are a number of studies that demonstrate the efficacy of prayer directed at nonhuman subjects including mice, yeast, bacteria, fungi, flagellates, plants, and seeds, and also for in vitro samples of human tissue, such as red blood cells and cancer cells (157). Comparatively, there are fewer studies involving human subjects, and the research methodology is generally weaker (158–160). Nevertheless, approximately one half of the stronger

studies showed some positive effect due to prayer. One of the best controlled studies (a randomized, double-blind study in which the patients, nurses, and doctors did not know the group assignment of the patients) demonstrated a strong, beneficial effect of prayer on coronary care unit patients. The prayed-for group was less likely to require antibiotics or endotracheal intubation, were less likely to develop pulmonary edema, and were less likely to die (161). Similar results were found in a more recent study in a similar setting (162). Prayer also had a positive effect on fertility rates and pregnancy rates after in vitro fertilization (163), general health of AIDS patients (164) and patients with anxiety, depression, and reduced self-esteem (165), but not on wound healing (166) or alcohol abuse patterns (167).

### Therapeutic Touch

Therapeutic touch (TT) is a technique first described in 1979 and developed by a nurse academician, Dolores Krieger, PhD, Professor of Nursing at New York University, and Dora Kunz, a natural healer. The practitioner uses the hands to sense and locate problems, and then serves as a conduit for universal energy, consciously transferring energy into the client's energy field in rhythmical, sweeping motions (168). TT is a credentialed nursing skill and it is taught in over 80 universities in over 30 countries.

### Qigong

Qigong (pronounced *chee-gong*) is an ancient philosophical system of harmonious integration of the human body with the universe (169). When qigong is practiced, the goal is to balance the qi or vital energy within the body, thus preventing or reducing energy imbalance which can give rise to illness. In self-administered qigong (internal qigong), the individual uses a variety of means, including breathing, visualization, and physical movements to bring the qi into balance. Qi can also be directed toward a recipient by a qigong practitioner, who consciously emits and directs the qi to another person (external qigong).

### Other Energy Therapies

The general healing nature of the qi is such as to suggest that it can be applied with some success to almost any medical or health problem. Rigorous research is sparse, but McGee and Chow relate a number of case studies for many different conditions, including stroke, paralysis, and cerebral palsy (170).

Reiki (pronounced *ray-key*) is a form of energy healing that usually involves a practitioner laying his or her hands slightly off of 12 specific locations on the body of the person being treated, allowing the “ki” or vital life force to flow through the Reiki practitioner into the body of the patient being treated (171). Having originated in Japan in the 1800s, Reiki has become an increasingly popular and accessible healing technique throughout the Western world. It can also be administered from a distance or self-administered. Training for the lowest level of “Reiki Master” is short in duration, making it an accessible form of energy healing. It is recommended by

the authors, however, that only practitioners with significant Reiki experience (5 years or more) or with training in an additional form of energy healing work with hospitalized or debilitated patients.

JSJ or “acupuncture without needles” is an energy healing technique which uses oriental pulse diagnosis and meridian theory to correct imbalances along energy channels. It is practiced one-on-one and is recommended for patients who may not tolerate acupuncture needles. Practitioners place their hands on specific combinations of acupuncture points to release energy blockages. In comparison to acupressure, there is significantly less emphasis on using physical pressure and more on adjusting the energy along the meridians. JSJ for self-administration is also taught in a 1-day format which allows the patient a wide range of applications. There are no side effects, making it safe for application on both mild and severely ill patients. A meta-analysis involving 24 randomized controlled or controlled clinical trials involving 1,153 participants examining energy therapies such as TT and Reiki for pain showed a modest effect on pain (172).

## **SPECIAL TOPICS: SPORTS MEDICINE, FUNCTIONAL MEDICINE, CAM IN THE INPATIENT SETTING**

### **Sports Medicine**

The role of the sports medicine physician is to return the athlete to play as quickly and safely as possible after injury and to prevent injury and illness. CAM therapies provide the sports physician with valuable tools to achieve these goals while avoiding the overuse of medications. The use of CAM is readily accepted by elite athletes: in a study of Division I NCAA Intercollegiate athletes, 56% of subjects reported using CAM over a 12-month time period, higher than the prevalence of CAM used by all adults in the United States (36%) (173).

Some of the more commonly used modalities are acupuncture, manual therapies (massage, osteopathic manual therapies, and chiropractic), homeopathic preparations, nutritional supplements, meditation and visualization techniques, and movement therapies (Alexander, Feldenkrais, Yoga) for the treatment or prevention of injuries. In this brief review, only acupuncture, use of nutritional supplements for muscle recovery, homeopathic remedies, and movement therapies, all discussed more fully above, are addressed.

Acupuncture is widely available and used by athletes at all levels for acute and chronic musculoskeletal conditions. In the office setting or on the sidelines, it is used in acute injuries for the rapid reduction of pain and swelling. This treatment of injuries within the first 48 hours is referred to as a tendino-muscular treatment (3). Used on a regular basis for nonacute conditions, acupuncture is helpful for restoration of flexibility, joint pain, and ligament sprains. Although tempting from the point of view of symptom relief, treatment immediately prior to athletic activity is discouraged. This is because acupuncture induces a state of deep relaxation associated with enkephalin

and dynorphin release, which could decrease alertness and place the athlete at risk for injury. A properly trained and licensed physician/acupuncturist should perform all treatments.

Proper nutrition and adequate caloric intake are extremely important in ensuring optimal performance. Athletes are strongly encouraged to follow the guidelines and basic principles of the anti-inflammatory diet (above). A sports medicine dietitian/nutritionist with background in the nutrition and physical requirements of a particular sport is an integral part of the elite athlete's sports medicine team, and should design a basic team program with modifications for each athlete based on caloric intake, gender, metabolism, and sport-specific needs. The same parameters are used in considering supplements. Athletes should, of course, be replete in basic vitamins and minerals; a few of greater importance to athletic performance are outlined here: L-Carnitine (1 to 3 g/d) and creatine (2 g/d are used as aids to recovery from exercise (174); creatine also helps build muscle tissue (175). There are various minerals advocated for use in athletes, especially those who experience greater loss due to excessive sweat. The majority of athletes can obtain adequate amounts with a well-balanced diet (176). Low levels of magnesium and sodium have been implicated in exercise-induced muscle cramps and poor exercise performance (176). It should be noted that serum magnesium levels are not a good measure of magnesium status; monocyte leukocyte magnesium or urine levels after a magnesium challenge have been recommended as a better measure of actual magnesium levels (177,178). Various anti-inflammatory and antioxidant supplements described previously may be incorporated in the athlete's regimen.

Homeopathy is described above and offers a few powerful agents for the athlete: Traumeel (a mixture of homeopathic agents) and Arnica Montana are used commonly for soft-tissue sprains and soft-tissue injuries (179). Alexander and Feldenkrais techniques and Yoga, described above, are movement therapies that increasingly have a place in the treatment of sports injuries. These are especially helpful in restoring or implementing efficient movement patterns which help the athlete heal and prevent injuries. The author Lisa Bartoli DO incorporates yoga, nutrition, Alexander, and acupuncture to improve strength, flexibility, and balance and as part of the recovery and treatment of injuries in elite rugby players, runners, and bicyclists.

### **Functional Medicine**

Functional medicine is an emerging approach to complex and chronic disease. The term was first coined in 1993 by Jeffrey Bland, PhD, nutritional biochemist and previous Director of Nutritional Research at the Linus Pauling Institute of Science and Medicine. Functional Medicine is an emerging paradigm that, instead of focusing on the primacy of pathology and differential diagnosis, focuses on the antecedent physiological processes that ultimately find their expression in health and disease. This concept of “upstream medicine” was first elaborated by Leo Galland, MD, in his unpublished but widely disseminated paper, *Patient Centered Diagnosis: A Guide to the Treatment of Patients as Individuals* and published in 1997

as *The Four Pillars of Healing* (180). The tenets of functional medicine are on the leading edge of ideas beginning to be recognized by mainstream medicine and include

1. Biochemical individuality of the human being leading to the need for personalized medicine that is not necessarily best served by the double-blind randomized controlled study or an assembly line approach to medicine.
2. A patient-centered rather than disease-centered approach.
3. The search for dynamic balance among the internal and external factors in body/mind/spirit.
4. Familiarity with the weblike interconnections of all human biology.
5. Identification of health as positive vitality, not merely the absence of disease.
6. Promotion of organ reserve as a means to expand the health span (181).

Functional medicine reflects a systems biology approach to health care; a comprehensive analysis of the manner in which all components of the human biological system interact functionally with the environment over time (182,183). Just as the physiatrist recognizes multiple interdependent macro aspects of function such as impairment, disability, and handicap, the functional medicine practitioner considers human function on a more fundamental level. These include processes such as communication inside and outside the cell, bioenergetics and energy transformation, issues of replication, repair and maintenance, structural integrity, elimination of waste, protection and defense, issues of transport and circulation, and the influence of environmental inputs such as nutrients and pollutants, as well as psychosocial stressors and the influence of both past physical and psychological trauma. All of these factors determine where the individual sits with respect to the continuum between vitality and disease. Nutritional medicine or “food as medicine” is a central hub of the functional medicine approach.

An example of how a physiatrist may practice functional medicine is the approach to a patient with osteoarthritis who wants to avoid surgery. In addition to recommending weight loss and physical therapy, the physiatrist would request detailed information on concurrent medical conditions, family history of inflammatory and other disease, lifestyle, environment, and nutrition habits. Laboratory values for basic chemistry, metabolic indicators, nutrients, and toxic substances would be evaluated. If suspected, gluten and other food sensitivities, which can result in an overall increase in inflammatory load, would be ruled out. Nutritional, pharmaceutical, and lifestyle interventions would be implemented to return the patient to optimal functioning on structural, biochemical, and mental-spiritual levels. This is but one example of where a comprehensive approach and dietary modification may have a profound effect on health.

Because both psychiatry and functional medicine see the patient with chronic disease at the center of a complex web of interactions, psychiatrists and their patients may find this approach intellectually and clinically rewarding.

## Use of CAM Techniques in the Inpatient Setting

CAM therapies are increasingly integrated into standard rehabilitation care. An example of integration of CAM therapies into this setting is the Atlantic Rehabilitation Institute in New Jersey. Inpatients are offered chair yoga and T'ai Chi by rehabilitation professionals in conjunction with standard rehabilitation care, and have the option of participating in daily qigong class, art therapy sessions, sitting quietly in a dedicated meditation space, or requesting one-on-one massage or energy treatments. Outpatients are referred for yoga, T'ai Chi, stress reduction, or nutritional counseling after PT and OT to help maintain gains made during the formal rehabilitation period, or for acupuncture to complement their current post inpatient physical therapy. Advantages of using CAM modalities within a rehabilitation hospital include increased variety of modalities, ability to treat across the continuum of care, and increased patient interest and confidence. Barriers to integration of conventional and CAM therapies include lack of established standards for practitioner licensing for some modalities, absence of protocols for management of specific conditions, and inconsistent third-party reimbursement. Suggestions for minimizing such barriers include hiring practitioners with experience in both conventional and complementary management of chronic musculoskeletal conditions, informed oversight and education of practitioners, ongoing education of therapists, physicians, and third-party payers. While integration of CAM therapies into the rehabilitation setting is in its infancy, it holds great promise for expanded management options and patient satisfaction.

## CONCLUSIONS

The judicious use of complementary therapies to supplement standard medical interventions has been a hallmark of the psychiatric approach, often under the supervision of a multispecialty team of caregivers. The techniques discussed in this chapter represent only a sampling of the many potentially useful complementary therapies available in a rehabilitation setting. Some techniques, such as acupuncture, phytotherapies, and nutritional supplementation, already have bodies of research that suggest their usefulness in this setting. Other techniques are in an earlier stage of validation. With a historically holistic approach to patient care and the increasing demand for physician-patient partnership and for natural options for prevention and treatment of chronic disease from an aging population, the field of PM&R is perfectly positioned to continue to lead the way in integrating CAM therapies and a holistic approach to patient care into mainstream medicine.

# Scientific Advances

# Evidence-Based Practice in Rehabilitation (Including Clinical Trials)

*Knowing is not enough; we must apply. Willing is not enough; we must do.*

Goethe, 1829

## INTRODUCTION

### History and Background

The importance of infusing scientific research into medical education and clinical care was emphasized in the Flexner Report, published in 1910. As Abraham Flexner noted: “If the sick are to reap the full benefit of recent progress in medicine, a more uniformly arduous and expensive medical education is demanded” (1). This observation coincided with numerous scientific breakthroughs that led to repudiation of folk treatments, such as bleeding and purging, in favor of treatments based on scientific method. To meet new challenges, modern medicine developed education standards that emphasized clinical practice and scientific research (2). However, with this innovation, research and clinical practice remained somewhat isolated in separate realms until the emergence of evidence-based medicine.

Evidence-based medicine bridges the gap between clinical practice and research and provides a method to systematically select and apply research findings as part of the clinical decision-making process. Using principles and methods derived from clinical epidemiology, the founders of evidence-based medicine sought to ground medical decision making in rigorous scientific evidence to invalidate previously accepted but ineffective diagnostic tests, prognostic protocols, and clinical treatments and replace them with new, more powerful, accurate, efficacious, and safer ones (3).

Evidence-based medicine offers a framework and objective methods for making clinical decisions by embedding research in the clinical decision-making process. Consequently, evidence-based medicine promotes the translation of research into practice and provides a mechanism for insuring that research evidence informs clinical decisions (4).

Over the last decade evidence-based medicine attracted considerable attention because it meets an identified need. As noted in the 1990 Institute of Medicine report, *Crossing the Quality Chasm*, an evidence-based approach to clinical practice

provides a sound method for making clinical decisions; reduces idiosyncratic variations in practice; and bridges the gap between knowledge and practice (5).

Despite the potential benefits, there are concerns about the movement towards evidence-based medicine. A literature survey of 47 articles published from 1966 to 1999 noted the most commonly cited barriers to evidence-based medicine: the need to develop new skills; difficulty applying evidence to the care of individual patients; and limited time and resources (6). Over the last 10 years, an explosion of practice resources to support evidence-based practice, which are available via the Internet (Tables 80-1 and 80-2), addressed some of the perceived barriers. These web-based resources provide clinicians with evidence-based practice background information, references, and self-study guides. Clinicians have easy access to evidence summaries and reviews that meet specific quality criteria. Many reviews also include a “clinical bottom-line” that summarizes the clinical importance of the evidence presented.

Criticisms of evidence-based medicine also include the following misperceptions: evidence-based medicine devalues clinical experience, ignores patient values and preferences, and is a cookbook approach to medicine (6). However, these misperceptions do not reflect the true spirit of evidence-based medicine. Dr. David Sackett, one of the founders of evidence-based medicine, states: “Evidence-based medicine is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients” (7). Evidence-based medicine does not blindly adhere to specific criteria for patient care. Rather, it serves as an adjunct to clinical decision-making. Finally, evidence-based medicine is not limited to use of randomized controlled trials. Evidence-based decision making emphasizes finding the *best available evidence*. The evidence is then critically appraised and the relative strengths and weaknesses are considered before applying the findings to clinical practice.

Evidence-based decisions are defined as the integration of best research evidence with clinical expertise and patient values (7). A model for evidence-based clinical decisions emphasizes three elements—*clinical state and circumstances*, *patient preferences and actions*, and *research evidence*—along with the fourth element, *clinical expertise*, that overlies the other three

Summarizes levels of evidence with specific criteria for evaluating evidence

(Fig. 80-1) (8). This model recognizes the important role that clinical expertise plays in the clinical decision-making process. Clinical expertise is required to size up the patient's clinical state, communicate with patients to determine their preferences, and determine how to best apply research findings to the individual patient (8).

### Challenges to Adopting an Evidence-Based Approach in Rehabilitation Practice

There are several challenges to adopting an evidence-based approach in rehabilitation. Evidence-based medicine was developed for use in general medicine and focuses on mortality or the presence or absence of disease. In contrast, rehabilitation medicine is a unique area of medicine that focuses on functioning, both as an outcome and an area for clinical assessment (9). A unifying model for rehabilitation, developed based on the International Classification of Functioning Disability and Health (ICF) framework, defines rehabilitation as a health strategy that aims to help people "achieve and maintain optimal functioning in interaction with their environment" (10). Because the focus of rehabilitation is so different from general

medicine, it is often difficult to translate evidence-based medicine concepts into a framework that is useful for rehabilitation. Another problem is that evidence-based medicine requires

**FIGURE 80-1.** Model for evidence-based clinical decisions. (Reproduced from Haynes RB, Devereaux PJ, Guyatt GH. Clinical expertise in the era of evidence-based medicine and patient choice. *Evid Based Med.* 2002;7(2):36–38.)

knowledge of clinical epidemiology (11), a field that deals with the solution of clinical problems using epidemiologic methods (12). Few rehabilitation professionals are trained in clinical epidemiology and must acquire evidence-based medicine skills independently through continuing education or self-study. These issues notwithstanding, the evidence-based medicine model has much to offer rehabilitation.

Over the last decade evidence-based medicine has been widely adopted by health care disciplines and is now commonly referred to by a more generic term—evidence-based practice. It is important that the rehabilitation field considers ways to infuse the principles of evidence-based practice into clinical practice. This chapter has the following aims: inspire rehabilitation professionals to adopt an evidence-based approach; help translate evidence-based medicine into terminology that is meaningful to the rehabilitation field; and provide strategies to implement an evidence-based practice approach to clinical practice.

### The Evidence-Based Practice Process

Figure 80-2 presents a schematic diagram of the steps involved in the evidence-based practice process. As the figure

**FIGURE 80-2.** The evidence-based practice process.

illustrates, evidence-based practice is patient focused. The first five steps in the evidence-based practice—identifying the learning or development need, asking a focused question, searching for evidence, applying research evidence, and critically appraising evidence—begin and end with the patient. A sixth step, evaluating the use of evidence, adds a quality improvement component to the process. Clinicians interested in adopting an evidence-based approach will find a variety of resources on Internet. Table 80-2 summarizes Internet resources that serve as a guide to each step of the evidence-based practice process.

### Step 1: Identify Learning or Development Need

The first step in the evidence-based practice process is to identify the learning issue and select the category of research evidence appropriate for the issue. For example, the learning issue may be uncertainty about which tests or clinical examination findings to consider in determining the presence or absence of a disease, impairment, or disorder—*evidence related to diagnosis*. A learning issue may arise when the patient inquires about the ability to return to work or the family inquires about the likelihood of a patient being able to return to home or to her/his previous level of functioning—*evidence related to prognosis*. Questions about other rehabilitation interventions that may yield a better outcome present another type of learning issue—*evidence related to intervention*. For each category of evidence—diagnosis, prognosis, or intervention—it is important to understand specific evidence-based practice concepts and terms.

### Step 2: Ask a Focused Question

Once the learning issue and the appropriate category of research—diagnosis, prognosis, or intervention—are identified, a focused clinical question is formulated. A clinical question consists of four parts: patient, intervention, comparison, outcome (PICO). Table 80-3 provides an example of the four-part clinical question. Clinical questions are constructed for each category of evidence. For example, a question related to diagnosis is framed as: For patients with shoulder pain, can clinical tests, compared to arthroscopy identify patients with rotator cuff tears? A question related to prognosis is posed: For patients with a quadriceps contusion injury, can clinical tests predict the time to return to sports? And a question related to intervention is structured: For elderly individuals with chronic disease, can a strength training exercise program reduce disability? Thus, a well-constructed clinical question establishes a link between patient problems, research evidence, and the clinical decision.

### Step 3: Search for Research Evidence

Medicine has witnessed tremendous growth in research over the last century and this growth is particularly evident in the volume of available information. Each year Medline indexes over 560,000 new articles and the Cochrane Center adds 20,000 new trials. The volume of information presents a challenge because published research includes many preliminary or exploratory studies. Knowledge that has been rigorously tested and is of sufficient importance to influence practice represents only a small fraction of the published research (13). Thus, we do not suffer from a lack of information but from an inability to efficiently process and organize the plethora of available information. Evidence-based practice provides useful strategies for the daunting task of keeping up-to-date on research literature. There are three strategies for conducting an effective and efficient search: (a) organize the search based on the hierarchy of research evidence quality; (b) use evidence-based practice search engines; and (c) search for evidence that has been summarized and rated for quality.

### Research Evidence Hierarchy

Since the goal of evidence-based practice is to apply the best available evidence, the literature search begins by looking for the highest quality evidence. A key concept in evidence-based practice is that research evidence is not equal in value. Evidence-based practice ranks research evidence based on a hierarchy that considers the degree to which the study design reduces bias and threats to validity. Professional organizations and evidence-based practice work groups have devised specific guidelines for rating evidence (14) that reflect the following values: controlled studies are ranked higher than uncontrolled studies; prospective studies are considered stronger than retrospective studies; and randomized studies are better than nonrandomized studies (15). Based on quality considerations, research evidence is categorized on a scale from Level I to V: high quality research with strong methodology is rated at the highest level (Level I) and expert opinion is ranked at the lowest level of evidence (Level V). Studies with weaknesses in research design and implementation or large confidence intervals (CIs) are ranked as Level II to IV.

*Systematic reviews* play an important role in evidence-based practice. In contrast to traditional opinion-based literature reviews, systematic reviews use a specific protocol to identify, critique, and summarize relevant studies that address a similar clinical question. Bias is minimized in systematic reviews because a comprehensive and reproducible process for searching the literature is outlined. Systematic reviews also assess the methodological quality of studies (16), which is defined as

**TABLE 80.3 Four-Part Clinical Question**

	<b>P</b>	<b>I</b>	<b>C</b>	<b>O</b>
Elements	Patient problem/ learning need	Intervention, diagnosis or Prognosis	Comparison (if indicated)	Outcome

“all aspects of a study’s design and conduct can be shown to protect against systematic bias, nonsystematic bias, and inferential error” (17).

It is important to consider the type of research—diagnosis, prognosis, or intervention—when evaluating the strength of research evidence. For all types of evidence, a valid systematic review of quality research is the highest level of evidence while expert opinion is the lowest. However, for the other levels of evidence, the criteria for research quality are somewhat different for diagnosis, prognosis, or intervention studies. Evidence related to diagnosis compares the diagnostic test results to a “gold” standard, which is generally an accepted proof of the presence or absence of the disease or disorder. Therefore, an important consideration for ranking evidence from diagnostic studies is to determine how the gold, or reference, standard is applied (15). Studies where the gold or reference standard is consistently applied blindly or objectively to all subjects are ranked higher than studies where the reference standard is not consistently applied. Furthermore, studies that validate diagnostic test results from a previous study are ranked higher than exploratory studies (14). Prognosis studies are concerned with examining the effect of patient characteristics on outcomes (15). Inception or prospective studies are rated higher than retrospective studies or studies using untreated subjects from randomized controlled trials (14). Intervention studies evaluate the effect of treatments on outcomes. Randomized controlled trials help to eliminate potential bias and studies using randomized controlled trials are rated higher than cohort and case-controlled studies.

Based on the hierarchy of research evidence, an efficient literature search strategy begins by looking for systematic reviews that summarize the results of many different studies and provide an overview of the body of research evidence that addresses a clinical question. If no appropriate systematic reviews are located, the search continues by focusing on specific well-designed individual studies until the best studies are located.

### **Search Engines**

The evidence-based practice movement spawned the development of search engines designed to streamline the literature search process. Some search engines incorporate an evidence-based practice framework. The search is organized by the type of research evidence and the results are presented in order, based on the hierarchy of research evidence. One useful resource is SUMsearch, which is described as a “meta” search engine because it searches multiple databases. SUMsearch results are then organized according to the hierarchy of evidence. SUMsearch is a good starting point for conducting a literature search because it is an efficient strategy for viewing a summary of the available evidence in a specific area and it is especially effective for locating information on systematic reviews and guidelines (18).

Databases of systematic reviews can also be searched directly. The Cochrane Collaboration, an international group dedicated to combining similar randomized trials to produce a more statistically sound evidence through systematic reviews,

is one of the best resources for systematic reviews. Complete systematic reviews require a subscription, but abstracts of the reviews are available via a searchable database at Cochrane website. The Cochrane Library includes reviews for the top ten causes of disability in developed and developing nations and, therefore, it is an important resource for evidence-based rehabilitation (19). Moreover, the Cochrane Collaboration includes the study groups dedicated to examining topics relevant to rehabilitation such as bone joint and muscle trauma, movement disorders, multiple sclerosis, musculoskeletal and neuromuscular disorders, and stroke (20).

If the search fails to yield a relevant and valid systematic review or evidence summary, the next step is to search the primary literature. PubMed, a service of the U.S. National Library of Medicine and the National Institutes of Health, provides an extensive database of research abstracts (21). PubMed is widely recognized as the best resource for information from original studies (18). PubMed recently added an evidence-based medicine search filter termed “clinical queries.” This feature allows the user to conduct a search based on the category of evidence (diagnosis, prognosis, or therapy) and to request results that are “focused” to include a few of the most relevant studies (specific) or “expanded” to include a wider range of studies (sensitive).

### **Evidence Summaries**

Another search strategy for busy clinicians is to search for evidence that has already been summarized and critiqued. The evidence-based practice movement fostered the development of secondary resources or “predigested” evidence summaries (see Table 80-2). Evidence summaries help to address concerns that evidence-based practice demands too much time and requires research critiquing skills beyond the ability of most clinicians. One example, the Database of Abstracts of Reviews of Effects (DARE), is a free, searchable database that includes evidence summaries relevant to rehabilitation (22). Each summary must meet specific quality criteria to be included in the DARE database. The evidence summary reviews key elements of the study and concludes with a critical commentary on the study. Discipline-specific evidence summaries are also available. The Physiotherapy Evidence Database (23) comprises abstracts of evidence-based clinical practice guidelines, systematic reviews, and clinical trials. The methods for the clinical trials are reviewed and rated on a ten-point scale (23). OTseeker is another database with abstracts of systematic reviews and clinical trials relevant to occupational therapy. The clinical trials are rated on an eight-point internal validity score and a two-point statistical reporting score (24). Online journals, such as APC Journal Club and Evidence-Based Medicine, also summarize results of clinical trials. Secondary sources present clinically relevant research that has been critically appraised and provide an important resource for busy clinicians. However, it is still important to examine the source and consider the validity and accuracy of the research summary and appraisal. Evidence summaries streamline the evidence-based practice process by simplifying the critical appraisal of evidence, which is described in the next step.

### Step 4: Critically Appraise the Evidence

Once the highest level of evidence for a specific clinical question is located, the evidence is critically appraised. The first item of the critical appraisal process is to assess the validity of the research evidence. Unfortunately, specific standards for determining the validity of a study have not been established and a proliferation of critical appraisal tools has led to considerable confusion. One systematic review identified 121 published critical appraisal tools. While the tools vary somewhat, the most frequently cited areas evaluated to establish the validity of research evidence for efficacy studies were: eligibility criteria, appropriate statistical analysis, random allocation of subjects, consideration of outcome measures used, sample size justification/power calculation, study design reported, and assessor blinding (25). The critical appraisal process, which varies for different types of research evidence, is described in the following sections.

### Systematic Reviews and Meta-Analyses

Similar to systematic reviews, meta-analyses use a specific protocol to locate and assess research articles addressing a specific question. However, meta-analyses go one step further by combining data to yield a summary statistic. The focus of the meta-analysis or systematic review should be clear with detailed information on the population, intervention and outcomes. Systematic reviews should meet criteria for establishing homogeneity. Specifically, the studies should be similar in terms of patient characteristics (e.g., age, type of disease/disorders), interventions used, outcomes measured, and the study methods (e.g., randomized trials, cohort studies) (26). The search strategy used to identify research articles should include multiple search engines to ensure that all relevant studies are considered (27). The process used to include studies should be outlined and the criteria used to evaluate studies clearly stated (28). Each study should be evaluated in terms of the methodological quality, precision or the width of the CI around the result and the external validity, or the extent to which the results can be generalized (27).

As the number of systematic reviews continues to grow, it is important to ensure that the information is up-to-date. Unfortunately, there is little research to support how and when

to update systematic reviews, so it is important to consider if the information presented is still relevant (29).

### Evidence Related to Diagnosis

Evidence related to diagnosis is concerned with determining the extent to which tests for specific conditions are able to distinguish individuals with and without a specific disease, impairment, or disorder. Results from the diagnostic test and the “gold” standard are organized in a  $2 \times 2$  contingency table and analyzed to determine how well the diagnostic test sorts patients into the appropriate “bins,” based on findings from the “gold” standard test. Often clinical tests are compared to an invasive surgical, radiological, or electrodiagnostic “gold” standard test; therefore, substituting a less invasive or less expensive clinical test is preferable. There are four possible outcomes when a diagnostic test is evaluated (Table 80-4): A—the test is positive and correctly identifies persons with the condition; B—the test is positive but the person does not have the condition; C—the test is negative but the person has the condition; D—the test is negative and the person does not have the condition.

The ability of a diagnostic test to correctly identify patients with a disease, impairment, or disorder is termed the test’s *sensitivity*, which is calculated as the proportion of patients with the disorder who have a positive test result. The test’s ability to identify patients without a disease, impairment, or disorder is termed as the test’s *specificity*, which is calculated as the proportion of patients without the disorder who have a negative test result. Ideally, tests are sufficiently sensitive and specific so that individuals with the disease, impairment, or disorder are identified and receive the appropriate interventions and individuals without the disorder are identified and not subjected to unnecessary treatments or restrictions.

*Likelihood ratios* combine sensitivity and specificity and provide another way to summarize the value of a diagnostic test. A positive likelihood ratio is the odds that a patient with a condition will have a positive test result compared to a patient without the condition. A negative likelihood ratio is the odds that a patient without a condition will have a negative clinical test result compared to a patient with the condition.

**TABLE 80.4** Contingency Table: Summarizing Results From a Diagnostic Test

	“Gold” standard identifies that disease/disorder is present	“Gold” standard identifies that disease/disorder is absent	Total
Test positive	A: Correct identifies condition	B: Incorrect over identifies condition	A + B
Test negative	C: Incorrect misses condition	D: Correct identifies absence of condition	C + D
Totals	A + C	B + D	

Sensitivity =  $A/A + C$ .

Does a test correctly identify when the condition is present?

Specificity =  $D/B + D$ .

Does a test correctly identify absence of the condition?

The *positive predictive value* is the proportion of patients with positive test results who have the condition and *negative predictive value* is the proportion of patients with negative test results who do not have the condition. Positive and negative predictive values provide a simple and clear way to represent diagnostic findings; however, because these values are affected by prevalence they must be interpreted with caution. A high prevalence will inflate the positive predictive values and lower the negative predictive values. Conversely, a low prevalence will lower the positive predictive value and inflate the negative predictive value. *Prevalence*, or pretest probability, estimates how common a disease or disorder is in the population. Prevalence estimates are derived from the study sample, the literature, or data from a specific clinical setting.

Several criteria must be met to establish the validity of research on a diagnostic test. First, the study should include an independent, blind comparison of the diagnostic test with a “gold” standard. It is important to critique the “gold” standard to ensure that it is, in fact, an accurate measure of the presence or absence of a disease or condition and that it was consistently applied to all test subjects. Next, consider the study design and characteristics of the subjects. Ideally, a prospective cohort design is used and the sample includes subjects who represent the continuum of severity for the disease or disorder. If a study includes subjects without symptoms or is comprised mainly of subjects with severe symptoms, the study may misrepresent the ability of the diagnostic test to identify persons with and without the disease or disorder. Before applying the results of a diagnostic study, examine the characteristics of the subjects to be sure that they are similar to the patient group for whom you intend to use the diagnostic test. Also, examine the methods section to determine if the diagnostic test was conducted in a manner consistent with its intended use. Finally, determine if the test was validated in a second, independent group of patients. If all of these criteria were met, the validity of the diagnostic study is established (30).

The next question is to determine the clinical importance of the diagnostic test by examining the ability of the test to correctly categorize patients with the condition of interest. Individual research studies may report results in terms of sensitivity, specificity, likelihood ratios, or predictive values (31). If results of the diagnostic study are not reported using the desired statistics, it may be possible to extract relevant data and calculate the variables of interest. With the use of calculators, which are available online, it is relatively easy to calculate different diagnostic variables.

Results from tests with continuous numeric scores can also be used to categorize patients for diagnostic purposes. A specific score is used as a cut-off point and patients with scores above or at and below the cut-off point are categorized based on the presence or absence of a trait, condition, or functional ability. For example, a prospective study followed elderly individuals for 1 year and used their scores on the Tinetti balance scale to identify elderly individuals who fell within the year (32). A *receiver-operator characteristic curve*, which plots sensitivity and

**FIGURE 80-3.** Receiver-operator characteristic curve for Tinetti balance test scores and fall status.

1-specificity of the different test scores, was examined to select a cut-off score that maximized the sensitivity and specificity of the test. As noted in Figure 80-3, a cut-off point score of 33 on the Tinetti scale yields a sensitivity of 51% and a specificity of 74%. This means that only 51% of elderly subjects with Tinetti scores at or below 33 were correctly identified as fallers, while 74% of nonfallers were correctly categorized. Increasing the cut-off point to a score at or below 36 increased the sensitivity to 70%. With a more stringent cut-off point more fallers were correctly identified. As noted in the previous example, sensitivity increases when the test is effective in ruling out the disorder. However, the increase in sensitivity was accompanied by a loss of specificity; now only 52% of nonfallers were correctly identified. This example illustrates the importance of considering the goal of the diagnostic test when selecting a cut-off point.

An example of a critical appraisal of a diagnostic study is presented in Table 80-5. In this study, clinical tests are compared to the “gold” standard that used joint arthroscopy to identify which patients had rotator cuff tears. This example shows that the clinical tests have low sensitivity (24%). Of the 200 patients with confirmed rotator cuff tears, only 48 were correctly identified with the clinical tests. The clinical tests were negative in 152 cases where arthroscopic findings showed a confirmed rotator cuff tear. Thus, a negative result on this clinical test was not effective in ruling out this condition. The sensitivity of a test increases when a *negative result* is able to *rule out* a disease or disorder. In this example with low sensitivity, more than 75% of the cases with negative results actually had a rotator cuff tear. In contrast, the specificity for the clinical tests is high (99%). There was only one case where the clinical tests indicated a rotator cuff tear that was not confirmed

**TABLE 80.5 Critical Appraisal: Diagnostic Study****1. Is this diagnostic study valid? (7)**

Was there an independent, blind comparison with a reference (“gold”) standard of diagnosis?	Prospective study using arthroscopic results as the “gold” standard. The authors completed clinical tests prior to grouping by arthroscopic results.
Was the diagnostic test evaluated in an appropriate spectrum of clients (like those in whom it would be used in practice)?	Yes
Was the reference standard applied regardless of the diagnostic test result?	Yes
Was the test (or cluster of tests) validated in a second, independent group of clients?	Yes

**Interpretation:** This diagnostic study is valid.

**2. Are the results of this valid diagnostic study important?**

		“Gold Standard” diagnosis of rotator cuff tear by arthroscopy				Total
		Present		Absent		
Diagnosis of rotator cuff tear by three positive clinical tests: supraspinatus weakness, weakness in external rotation, positive impingement	Positive	48	<i>a</i>	<i>b</i>	1	49
	Negative	152	<i>c</i>	<i>d</i>	199	351
	Total	200		200		400

	Definition	Formula	Example
Sensitivity	Ability to correctly identify someone with the disorder	$\frac{a}{a+c}$	$\frac{48}{48+152} = 0.24 = 24\%$
Specificity	Ability to correctly identify someone without the disorder	$\frac{d}{b+d}$	$\frac{199}{1+199} = 0.995 = 99.5\%$
Likelihood ratio (positive test result)	The likelihood that a positive test result was observed for someone with a rotator cuff tear compared to someone without a rotator cuff tear.	$\frac{\text{sens}}{1-\text{spec}}$	$\frac{0.24}{1-0.995} = 48$
Likelihood ratio (negative test result)	The likelihood that a negative test result was observed for someone without a rotator cuff tear compared to someone with a rotator cuff tear.	$\frac{1-\text{sens}}{\text{spec}}$	$\frac{1-0.24}{0.995} = 0.76$
Positive predictive value	The proportion of subjects with positive results who have confirmed rotator cuff tears.	$\frac{a}{a+b}$	$\frac{48}{48+1} = 0.98 = 98\%$
Negative predictive value	The proportion of subjects with negative test results who do not have confirmed rotator cuff tears.	$\frac{d}{c+d}$	$\frac{199}{152+199} = 0.57 = 57\%$
Pretest probability (prevalence)	How common is the diagnosis of rotator cuff tear within the population (of this study)?	$\frac{a+c}{a+b+c+d}$	Estimate patient’s pretest probability based on age (e.g., prevalence for ages 30–39 = 0.20)
Pretest odds	The odds of a rotator cuff tear before the tests are done.	$\frac{\text{prev}}{1-\text{prev}}$	$\frac{0.20}{1-0.2} = 0.25$
Posttest odds	The odds of a rotator cuff tear after the test has been carried out.	Pretest odds $\times$ +LR	$0.25 \times 48 = 12$
Posttest probability	The probability of a rotator cuff tear after the results are obtained	$\frac{\text{post test odds}}{\text{post test odds} + 1}$	$\frac{12}{12+1} = 0.92 = 92\%$ (or use nomogram)
Diagnostic accuracy	Percentage of people correctly diagnosed	$100 \times \frac{a+d}{a+b+c+d}$	$100 \times \frac{48+199}{400} = 61.7\%$

**TABLE 80.5** Critical Appraisal: Diagnostic Study (*Continued*)

CIs (95%)	Formula	Example
Positive predictive value	$SE = \sqrt{\frac{p \times (1-p)}{n}}$	$SE = \sqrt{\frac{0.98 \times (1-0.98)}{400}} = 0.01$
Note: This formula is also used for sensitivity and specificity	95% CI = $p \pm (1.96 \times SE)$	95% CI = $0.98 \pm 0.01 = 0.97-99$
Value of a Test—Based on Likelihood Ratio (54)		
+Likelihood Ratio	−Likelihood Ratio	Test Value
1.0	1.0	Useless (pretest probability = posttest disease probability)
1.0–2.0	0.5–1.0	Usually none to small
2.0–5.0	0.2–0.5	Small to moderate
5.0–10.0	0.1–0.2	Moderate to large
>10.0	0.0–0.1	Large

Adapted from Critical Appraisal Worksheets provided by the Centre for Evidence-Based Medicine, <http://www.cebm.utoronto.ca/practise/ca/diagnosis>.  
Murrell GAC, Walton JR. Diagnosis of rotator cuff tears. *Lancet*. 2001;357:769–770.

by arthroscopic findings. So it is likely that a patient with a positive test *does* have a rotator cuff tear. When a test has high specificity, a *positive result* is able to effectively *rule in* the target condition. This example demonstrates the importance of considering both sensitivity and specificity when selecting a diagnostic test. Because this test has high specificity, a positive result on the clinical tests is a good indication that the patient has a rotator cuff tear; however, due to the low sensitivity a large percentage of cases with negative test results will actually have a rotator cuff tear that is missed.

In this example, the positive likelihood ratio was large (48) and the negative likelihood ratio was useless (0.76). The positive predictive value showed that 98% of study subjects with positive clinical test results had rotator cuff tears and the negative predictive value showed that 57% of study subjects with negative tests did not have rotator cuff tears. However, the predictive values are affected by the prevalence of the condition. The pretest probability (prevalence) for rotator cuff tears for subjects between the ages of 30 and 39 was approximately 20%. After the three clinical tests were conducted and results obtained, the probability of having a rotator cuff tear increased to 92% and the overall diagnostic accuracy was 61.7%. The diagnostic information presented in this study can help clinicians understand the benefits and limitations of using clinical tests in patients with a suspected rotator cuff tear. This information can also be communicated to patients when explaining the clinical findings.

### Evidence Related to Prognosis

Clinicians directly consider questions about a patient's prognosis all the time. At times prognostic questions are posed by patients such as, "Will I regain my pre-fracture level of

function?" Or "How long will it take for me to recover from this injury and return to work?" At other times clinicians will consider prognosis less directly, such as when deciding where to discharge a patient at the end of an acute hospital stay. A question such as, "Is this patient a good fit for inpatient rehabilitation?" is often based on a clinician's judgment of prognosis. Prognosis reflects a clinician's estimation of a patient's likely clinical course over time taking into account the likely complications of their disease, injury, or impairment. There are several different aspects to prognosis: a *qualitative aspect* (i.e., What outcomes could happen to this patient?); a *quantitative aspect* (i.e., How likely are the outcomes to occur to this patient?); a *temporal aspect* (i.e., Over what time period are the anticipated outcomes likely to occur?); and an *evaluative aspect* (i.e., What is likely to influence the outcomes?).

In rehabilitation, clinicians frequently base their prognostic judgments and advice on their clinical experience and less often on the basis of scientific evidence. Later in this section, we will consider a framework for appraising the validity, importance, and applicability of evidence using similar guidelines applied to evidence regarding diagnosis and treatment.

To evaluate prognostic evidence, the clinician needs to appraise three distinct and important elements: the validity of the evidence, the importance, and the applicability of evidence to the patient(s).

In determining whether prognostic evidence is valid several different factors must be considered. First, the clinician must appraise if the evidence is based on a defined, representative sample of patients assembled at a common point in the course of their disease or episode of care (usually at the start). A second validity issue is the degree to which patient follow-up was complete and sufficiently long. This judgment must

be made in relation to the outcome being considered. A short follow-up with just a select few patients would not be sufficient evidence to use for advising patients. If the follow-up is long enough, the clinician still needs to assess which subjects entered the study but were lost to follow-up since a substantial loss to follow-up can significantly affect conclusions drawn about patient prognosis. For example, if patients who perform poorly are lost to follow-up this would introduce significant bias into any prognostic determination.

The next issue is whether objective outcome criteria were defined and tracked with adequate validity. To minimize the potential effects of bias in outcome measurement, objective criteria should have been established and implemented in the collection of outcome data. In the best case, those making outcome measurements are kept in the dark (i.e., blind) to a patient's clinical characteristics and prognostic factors to minimize the likelihood of bias creeping into the assessment.

Once the validity of a prognostic investigation has been established, the next issue is to determine its importance and appropriateness by examining the characteristics of the study subjects and evaluating the degree to which the prognostic information is relevant to an individual patient's situation and/or condition. Finally, CI around the prognostic estimate should be examined. A prognostic estimate with a relatively small CI provides greater assurance that the information will be important and useful to patients.

An example of a critical appraisal of a prognosis study is presented in Table 80-6. The study examined the ability of the Orpington prognostic scale (OPS) to predict functional recovery for patients at 3- and 6-months poststroke. The study met most validity criteria, but it was noted that patients with severe and mild symptoms were not well represented. Therefore, when this evidence is applied to an individual patient it is important to remember that the findings may differ for patients with

**TABLE 80.6 Critical Appraisal: Prognosis Study**

**1. Are the results of this prognosis study valid?**

Were the study subjects representative?	Yes—the sample consisted of patients with a broad age range with good representation of minorities. Subjects were drawn from 12 area hospitals. Rehabilitation occurred in a variety of settings.
Did the research study a broad spectrum of patients with the disorder?	No—patients with severe and mild stroke were underrepresented.
Were patients at a similar point in the course of their disease?	Yes—all subjects had baseline OPS measures completed between 3 and 14 d poststroke. Follow-up functional assessments were at 3- and 6-mo intervals.
Were researchers recording the outcomes blinded to the prognostic factors?	Not clear
Were outcomes well-defined and relevant? Were criteria for measuring outcomes preestablished?	Outcome measures were functional activities identified as important to individuals of both genders.
Were outcome measures established prior to the start of the study?	Yes
Was follow-up sufficiently long and complete?	Yes
What was the drop out rate? Were reasons for drop out documented?	Drop out rate was <20%. Reasons were documented. Characteristics of patients who did not complete the 6-mo follow-up indicate that they were more severely involved.
Did the authors adjust for differences between groups?	No

**2. Are the results of this prognostic study important?**

Prevalence of independence in functional activities based on OPS baseline score of 3.6

	3 mo	6 mo
Function	51%	64%
Personal care	95% CI = 47%–54%	95% CI = 56%–71%
Meal preparation	53%	60%
	95% CI = 45%–61%	95% CI = 52%–68%
Medication administration	54%	56%
	95% CI = 46%–61%	95% CI = 48%–63%
Community mobility	29%	38%
	95% CI = 22%–36%	95% CI = 30%–46%

Adapted from Critical Appraisal Worksheets provided by the Centre for Evidence-Based Medicine, <http://www.cebm.utoronto.ca/practise/ca/prognosis>.

Studenski SA, Wallace D, Duncan PW, et al. Predicting stroke recovery: three- and six-month rates of patient-centered functional outcomes based on the Orpington prognostic scale. *J Am Geriatr Soc*. 2001;49(3):308–312.

severe or mild symptoms. At 6-months poststroke, patients with initial OPS scores of 3.6 achieve the following levels of functional ability (note: range includes 95% CI): 56% to 71% were independent in personal care; 52% to 68% were independent in meal preparation; 48% to 63% were independent in medication administration; and 30% to 46% were independent in community mobility. This information can be useful when discussing expectations for functional outcomes with individual patients and their families.

### ***Evidence Related to Intervention***

Clinicians have many options in determining a course of care for their patients, but too often treatment decisions are based on a clinician's experience or preference. Many studies demonstrate disparities in clinical care and point to the need for more equitable and evidence-based care (5). The goal of evidence-based practice is to help clinicians work with their patients to select interventions that are likely to produce the desired outcomes, are worth the costs and the efforts of using them and fit with patient preferences. Evidence-based practice provides an objective framework and a systematic approach to guide the clinical decision-making process. Evidence-based practice focuses on determining the importance and clinical significance of research related to interventions so that their relative benefits can be better understood, communicated to the patient, and used to make decisions.

Critical appraisal of intervention studies begins by examining the outcome measure used in the study to determine if it is appropriate for answering the clinical question. Specifically, the dimension of outcome measure (e.g., impairment, functional limitation, disability) should match the outcome identified in the clinical question. It is also important to establish that the outcome measure used is valid and reliable.

The critical appraisal process continues by examining the methods section. Were subjects randomly assigned to groups? Were researchers (single) and, if possible, subjects (double) blind to group? Next, review the baseline characteristics and demographic information for the control and experimental groups to see if they are similar. If differences exist, could they affect the study results? Were subjects who withdrew or did not complete the study accounted for? And were subjects analyzed in the groups to which they were randomized (intention to treat analysis)?

Review the methods section to determine if both groups were treated equally, except for the experimental intervention. Determine if the follow-up was sufficiently long and complete. If the results were not statistically significant, the study should include a power analysis to determine if the number of subjects in the study was sufficient to find a difference if, in fact, one existed (33).

Once the validity of a study is established, the next step is to determine if the results are of a sufficient magnitude to warrant a change in practice. Research studies comparing outcomes for different interventions, typically, report results in terms of *statistical significance* or *p-values*. The statistical significance is determined before the study begins and, most

often, the significance level is set at  $p < 0.05$ . The *p-value* is the actual probability of obtaining the observed result if the null hypothesis (that there is no difference) is true. If the *p-value* is less than the identified significance level, the null hypothesis is rejected. Statistical significance is regularly reported in research studies and is the primary factor used to evaluate research findings. However, there is a difference between statistical significance and the magnitude of the treatment effect or *clinical significance*. Statistical significance conflates the magnitude of the difference between groups and the sample size. Since sample size affects statistical significance, a rather small treatment effect can yield statistically significant results if the sample size is large enough. Evidence-based practice focuses on the magnitude of the effect or clinical significance of research findings so that they can guide in clinical decision-making.

Results from an intervention study where data are reported as proportions can be summarized as the proportion of patients with good or bad outcomes. The *experimental event rate* (EER) and the *control event rate* (CER) represent the proportion of subjects who achieve the desired outcome in the respective groups. Using these values, one can determine the *relative benefit increase* (RBI), or increase in good outcomes in the experimental group. This useful statistic helps quantify the magnitude or clinical significance of the intervention. The EER and CER are also used to calculate the absolute benefit increase (ABI), which is the absolute difference between rates of good outcomes in experimental and control groups. Finally, ABI can be used to calculate the *number needed to treat* (NNT) to achieve one additional good outcome. The NNT calculation is a useful statistic that captures the effort required to see the effect of an intervention (34). Moreover, the NNT statistic, in conjunction with financial data, can be used to determine cost/benefit ratios.

In evidence-based practice examples, treatment effects are often described in terms of dichotomous variables, such as the proportion or percentage of subjects that lived/died or were cured/not cured. Rehabilitation outcomes are not usually defined in terms of life and death or cures but the following are examples of dichotomous variables that are relevant to the rehabilitation field: returning to work or not, being discharged to home or skilled nursing facility, or achieving a target level on a functional test or not. When dichotomous variables are reported as percentages or proportions, these data can be used to quantify the magnitude or clinical significance of the treatment effect by calculating the ABI and the NNT.

The NNT calculation is not often reported in rehabilitation literature; however, it is a useful calculation. For example, if the effectiveness of an intervention is examined based on the proportion of patients discharged to home versus skilled nursing facility, the NNT calculation can estimate the number of patients that would have to be treated with this intervention to yield one additional discharge to home. The NNT calculation helps answer questions about the efficacy and clinical importance of an intervention. It is reported with CIs to indicate the precision of the estimate. Because

NNT summarizes the effort required to produce positive outcomes it can be used to calculate the costs and benefits of an intervention (35).

If data in a study are summarized as means and standard deviations clinical importance is assessed by calculating the *effect size*, which considers the size of the difference between two groups relative to the variability of the outcome in the patient group without the confounding influence of sample size. The effect size, which is the standardized mean difference between two groups, is not often mentioned in research reports but is relatively easy to calculate (36).

$$\text{Effect size} = \frac{\left[ \begin{array}{c} \text{Mean of experimental} \\ \text{group} \end{array} \right] - \left[ \begin{array}{c} \text{Mean of control} \\ \text{group} \end{array} \right]}{\text{Standard deviation (pooled)}}$$

Effect sizes are reported with CIs and they are used to categorize the magnitude of the treatment effect as follows: *large* (anything >0.5), *moderate* (0.5 to 0.3), *small* 0.3 to 0.1, and *trivial* (anything <0.1). Knowledge of the effect size is helpful when determining if the evidence is strong enough to change practice. It is also important to consider other aspects of the research design when evaluating the strength of evidence. A small or moderate effect size may be more meaningful in rehabilitation research because the variability among subjects (standard deviation) reduces the effect size.

Evidence-based practice calculators can ease the burden of determining the clinical significance of research evidence. Free, online calculators are available for diagnostic tests, and for calculating the NNT and effect size (see Table 80-2).

An example of a critical appraisal of an intervention study is presented in Table 80-7. The study examines the effect of an individual counseling and self-management program on bed disability days in elderly individuals. The EER shows that subjects with one or more bed disability day at baseline had a 29% increase in the rate of improving the number of bed disability days compared to the control group. According to the ABI calculation, we can be 95% confident that the increase in the rate of good outcomes is between 11% and 47%. For every three elderly individuals who participated in the program, one additional person improved in bed disability days. The NNT calculation indicates that we can be 95% confident that we will see one additional good outcome for every two to nine elderly individuals who participate in the program. These calculations can help determine the importance and economic impact of interventions. This information can also be part of patient communication.

### Step 5: Apply Research Evidence

Applying research evidence to individual patients is one of the most challenging aspects of evidence-based practice. While specific rules and procedures serve as a guide in the preceding evidence-based practice steps, applying research evidence to individual patient cases requires sound clinical judgment. Indeed, applying evidence to patients assumes that results from research studies can be generalized when, in fact, patients

present with a wide range of differences (37). One of the greatest challenges of evidence-based practice is to determine how an individual patient's age, disease characteristics, or comorbidities, which may differ from subjects in the study sample, affect the applicability of the evidence. For this reason, clinical expertise is a critical component of evidence-based practice.

The eligibility criteria for subjects in clinical trials must be considered when applying research findings to individual patients. For example, effectiveness studies have wide eligibility criteria and participation is extended to a heterogeneous group of subjects. And, because the results were seen in a heterogeneous group of subjects, it is easier to make a case that similar results will be seen in a wide range of patients. In contrast, efficacy studies have narrow eligibility criteria and participation limited to a homogenous group of highly responsive patients (38). Consequently, one must be cautious about applying the results of an efficacy study to the general population that includes a range of individuals who are not likely to be as responsive (39).

Communication with patients to explain the options and determine their preferences is an important part of the decision-making process. The recent increase in consumerism and emphasis on patient-centered care reinforces the need to consider patient preferences when deciding on treatment choices. Patient involvement is a significant component of evidence-based practice and there are many related benefits. Active patient involvement in care is associated with improved outcomes and enhanced quality of life (40,41). Informed patients are more likely to participate in their care and make better decisions (42). Since patients and their families often have access to a wealth of information through the Internet, they frequently bring along the results of their searches and provide the impetus to begin a discussion of diagnostic, prognostic, and treatment options.

Clinicians can effectively communicate with patients by clearly summarizing research evidence, outlining treatment options, and discussing estimates of potential benefits and risks. The discussion should explore the patient's values about the therapy and potential options (39). It is important to build a partnership and understand the patient's experience and expectations. The discussion of evidence should include a balanced presentation of options and, after consideration of the clinical evidence and patient's values, the clinician can recommend an option and explain how the choice is consistent with the patient's values. Finally, it is important to make sure that the patient understands and agrees with the recommendation (42).

### Step 6: Evaluate the Use of Evidence

The final step in the evidence-based practice process involves an evaluation of the process and the use of evidence. The evaluation includes a reflection on how well the process worked. This step presents an opportunity to identify areas for improvement and to implement strategies for continued growth in becoming an evidence-based practitioner. The evaluation step also presents an opportunity to investigate the impact of evidence-based decisions to determine if changes in practice had an effect on outcomes.

**TABLE 80.7** Critical Appraisal: Intervention Study**1. Are the results of this therapy study valid?**

Was randomization maintained?	Yes
Were all patients who entered into the trial accounted for?	Yes
Were all patients analyzed in the groups to which they were randomized (intention to treat analysis)?	Yes
Were researchers (single) and patients (double) blind to treatment group?	Not specified, but data collectors were not involved in the intervention.
Were baseline characteristics of the two groups similar?	No, more intervention subjects were women, not married, living alone, had diabetes, were more restricted in activity days at baseline. Baseline status on outcome, gender, and age were adjusted in analyses.
Except for the experimental intervention, were both groups treated equally?	Yes, but difficult to control in this community-based study.
Was follow-up sufficiently long and complete?	Only 1 y. Previous study showed effects were not sustained after 1 y.
Was a power analysis performed?	Yes.
Level of evidence?	Individual randomized control trial.
Dimension of outcome measure? Are the measures appropriate for answering the clinical question?	Study includes administrative, impairment, activity, and participation measures; all are appropriate for answering the clinical question.
Were the measures valid and reliable and used in other studies?	Yes.

**Interpretation:** This intervention study is valid.

**2. Are the results of this valid intervention study important? How large and precise is the treatment effect?**

Number of bed disability days for patients with  $\geq 1$  bed disability day at baseline

	Improved		Same or Worse	Total
Experimental	7	<i>a</i>	<i>b</i> 17	24
Control	0	<i>c</i>	<i>d</i> 15	15
Total	7		32	39
Experimental event rate (EER)	Proportion of patients in the experimental group who showed a positive effect		$EER = \frac{a}{a+b}$	$EER = \frac{7}{7+17} = 0.29 = 29\%$
Control event rate (CER)	Proportion of patients in the control group who showed a positive effect		$CER = \frac{c}{c+d}$	$CER = \frac{0}{0+15} = 0 = 0\%$
Relative benefit increase (RBI)	Proportional increase in rates of good outcomes between experimental and control patients		$RBI = EER - CER/CER$	$RBI = 29 - 0/0 = \text{cannot calculate}$
Absolute benefit increase (ABI)	The absolute difference in rates of good outcomes between experimental and control patients		$ABI = EER - CER$	$ABI = 29 - 0 = 29 = 29\%$ 95% CI = 11%–47%
Number needed to treat (NNT)	The number of patients needed to be treated to achieve one additional good outcome		$NNT = 1/ABI$	$NNT = 100/29 = 4$ 95% CI = 2–9

95% CI for ABI.

$$95\% \text{ CI} = \pm 1.96 \sqrt{\frac{CER(1-CER)}{\text{No. of control pts}} + \frac{EER(1-EER)}{\text{No. of treatment pts}}}$$

$$95\% \text{ CI} = \pm 1.96 \sqrt{\frac{0(1-0)}{15} + \frac{0.29(1-0.29)}{24}} = 0.18.$$

$$95\% \text{ CI} = 0.29 \pm 0.18 = 11\% - 47\%.$$

95% CI for NNT (calculated from ABI).

$$100/\text{CI of lower limits of ABI} = 100/11 = 9.$$

$$100/\text{CI of upper limits of ABI} = 100/47 = 2.$$

Leveille SG, Wagner EH, Davis C, et al. Preventing disability and managing chronic illness in frail older adults: a randomized trial of a community-based partnership with primary care. *J Am Geriatr Soc*. 1998;46:1191–1198.

**TABLE 80.8 Evidence-Based Practice Self-Assessment<sup>a</sup>**

1. Identify learning issue	1.1. I reflect on my practice and identify learning needs.
	1.2. I identify categories of evidence that best address my learning need (e.g., diagnosis, prognosis, intervention).
2. Ask focused question	2.1. I generate four-part clinical questions in some categories.
	2.2. I frame four-part questions in all categories: diagnosis, prognosis, and intervention.
3. Search for evidence	3.1. I am aware of literature search engines and evidence-based practice databases.
	3.2. I understand the comparative strengths and weaknesses of different sources of evidence.
	3.3. I use different sources of evidence in practice.
	3.4. I select the appropriate sources to address learning issues and clinical questions.
	3.5. I design and conduct an effective and efficient search to answer a focused question.
4. Critically appraise evidence	4.1. I assess the relevance of study design to a specific clinical question (e.g., diagnosis, prognosis, intervention).
	4.2. I understand the meaning of commonly used terms in research (e.g., <i>p</i> value and CIs, effect size, power).
	4.3. I understand terms commonly used in clinical epidemiology (e.g., number needed to treat, sensitivity, specificity, predictive values and likelihood ratios).
	4.4. I can assess the internal validity of a study.
	4.5. I can derive summary statistics from research papers.
	4.6. I understand the principles and uses of meta-analyses and systematic reviews.
	4.7. I can assess the clinical importance of a study.
	4.8. I can conduct a systematic review.
5. Apply findings	5.1. I can assess the relevance of the synopsis/appraised study to the individual patient and to the policy.
	5.2. I can explain summary statistics in a manner appropriate to the patient's level of understanding.
	5.3. I can advocate for, plan, and implement a change of practice in a clinical setting (e.g., hospital, clinic, region).
6. Evaluate practice	6.1. I keep a record of questions to be answered.
	6.2. I organize CATs and practice information to allow efficient retrieval and application.
	6.3. My practice is informed and up-to-date.
	6.4. I build evidence-based practice into my organizational improvement plan.

<sup>a</sup>Modified from a presentation at the International Conference of Evidence-Based Health Care. Teachers and Developers (Sicily, Italy, September 2003).

## Becoming an Evidence-Based Practitioner

### Assessing Knowledge and Skill

The first step in becoming an evidence-based practitioner is to identify individual learning needs. Specific evidence-based practice competencies, such as searching the literature (43) and critical appraisal skills (44–46) are often assessed. Table 80-8 presents a list of evidence-based practice competencies that can be used as a guide to gaining knowledge and skill. Validated tests of evidence-based practice, such as the Berlin Test (47) or the Fresno Test (48), are available but they emphasize general medical cases and examples.

The prospect of developing all of the skills needed to be a competent evidence-based practitioner can seem overwhelming. It is not necessary to be accomplished in all areas of evidence-based practice, but it is important to start and continue to grow. It may also be helpful to consider stages of developing evidence-based practice abilities, as described below.

- Stage 1: I use evidence-based practice guidelines or protocols developed by colleagues but do not search the literature or critically appraise research.

- Stage 2: I seek and apply evidence-based summaries that give a clinical “bottom line” but I am not comfortable appraising and applying findings from primary literature.
- Stage 3: I have expertise in all evidence-based practice knowledge and skills. I am able to locate, appraise, and apply findings from primary literature and systematic reviews.

Considering evidence-based practice skills as stages makes it possible for every clinician to be an evidence-based practitioner, without mastering all areas of knowledge and skill.

### Implementation Strategies

The gap between evidence and practice is widely acknowledged (49) but the movement from best evidence to best practice is not simple. Strategies to become an evidence-based practitioner can be developed at three different levels: personal, professional group, and institutional. On a personal level, an individual clinician can identify knowledge gaps and learning issues. These learning issues can be addressed by collaborative efforts among colleagues, attending workshops and courses or by developing a self-study program using

TABLE 80.9	Evidence-Based Practice Implementation Strategies
<ul style="list-style-type: none"><li>• Develop a system to track clinical questions in your setting.</li><li>• Work evidence-based practice into scheduled activities (e.g., rounds, journal club, in-service).</li><li>• Incorporate evidence-based practice into staff education and student/residency programs.</li><li>• Establish an evidence-based practice work group.</li><li>• Make use of online evidence-based practice resources.</li><li>• Establish evidence-based practice competencies for your setting and include assessment in staff performance evaluation.</li><li>• Discuss evidence with patients as a component of patient education.</li><li>• Develop an evidence-based practice folder with CATs.</li></ul>	

Compiled from suggestions made by clinical educators at the Boston University Faculty Summer Institutes 2001 to 2003.

the online resources. Working to become an evidence-based practitioner can seem overwhelming for an individual, but working in a group where individuals contribute their expertise eases the burden. Organizing an evidence-based practice journal club is an excellent strategy for gaining knowledge and skill while working to create an evidence-based practice culture. Table 80-9 provides a summary of evidence-based practice implementation strategies.

A randomized controlled trial studying the effects of journal club participation on medical residents' evidence-based practice knowledge and skills showed the following significant changes: improved ability to critique the methods sections of articles; increased ability to read and incorporate medical literature in practice; and greater skepticism of results and conclusions (50). There are several strategies for creating effective journal clubs. It is important to have identified roles, particularly with respect to the facilitator and specific presenter. Group members can begin by assessing their evidence-based practice strengths and weaknesses. Then, the group can work together to share areas of expertise and capitalize on the strengths of group members (51).

Evidence-based practice work groups can develop systematic approaches to incorporate an evidence-based approach into scheduled activities. The group can identify a common place for recording clinical questions and select one question for critical appraisal and present the results during an in-service. A discussion of research evidence and patient preferences can also be incorporated into patient education activities.

There are also strategies at an institutional level to support creation of an evidence-based practice culture. The following steps are recommended: (a) begin by targeting a problem that is deemed important due to either a high prevalence or high cost; (b) synthesize information about optimal practice; (c) synthesize information about current practice; (d) identify discrepancies; (e) outline a practice improvement plan; (f) assess the

impact in terms of efficacy and cost; (g) decide to implement or not and continue improvement efforts (52).

## CONCLUSIONS

Evidence-based medicine, a term that was coined in the 1990s by a group of clinicians and epidemiologists at McMaster University in Ontario, Canada, has evolved into an international movement across all health care disciplines, including the disciplines that comprise the rehabilitation field. It is likely that a primary barrier to evidence-based practice—limited time—will be mitigated by advances in technology and the burgeoning evidence-based practice resources available via the Internet. As databases of evidence summaries continue to grow, one can imagine a future where clinicians routinely use wireless, hand-held devices for point-of-care access to relevant information that has been critiqued and summarized (53,54). Another barrier, limited knowledge of clinical epidemiology, will also have less of an impact as these methods are taught to future rehabilitation professionals.

There are several efforts that can support the continued growth of evidence-based practice in rehabilitation. The field would benefit from agreement on criteria for critiquing, evaluating, and grading the quality of rehabilitation research. Rehabilitation researchers should attempt to use evidence-based practice measures of clinical importance—NNT, effect size, likelihood ratios—to summarize data. And, finally, there is a need for better training in evidence-based practice, using relevant patient cases and tools to assess evidence-based practice knowledge and skills with examples from rehabilitation.

The quote by Goethe at the start of this chapter is an apt reflection of the challenge facing rehabilitation professionals. It is important to know about the latest advances in our field; however, knowing is not sufficient—knowledge of research must be applied. It is important to be willing to critically examine the care we provide to include the latest advances, but being willing is not enough—where evidence exists, we must take action to change practice.

## ACKNOWLEDGMENTS

This chapter includes many insights gained during the Faculty Summer Institute: Integrating an Evidence-Based Approach into Rehabilitation Professional Education. The Institute, sponsored by the Center for Measuring Rehabilitation Outcomes at Boston University and supported by the National Institute of Disability and Rehabilitation Research, was held for three consecutive years (2001 to 2003). The following individuals participated in the Faculty Institute and we acknowledge their contributions: Wendy J. Coster, PhD, OTR, Nancy Baker, ScD, OTR, Stephen M. Haley, PhD, PT, Julie Keysor, PhD, PT, Mary Law, PhD, OT(C), Robert Meenan, MD, MPH, Ken Ottenbacher, PhD, OTR, Hilary Siebens, MD, Patti Solomon PhD, PT, and Linda Tickle-Degnen, PhD, OTR.

# Neural Repair and Plasticity

Increasing evidence suggests that neural repair can support some degree of behavioral recovery in many forms of neurological disease. This chapter reviews these concepts, with an emphasis on stroke and on motor deficits. Stroke remains a leading cause of adult disability and illustrates many of the key points. Some degree of spontaneous behavioral recovery is usually seen in the weeks following stroke onset. Animal studies have provided insight into underlying molecular and physiological events. Brain mapping studies in human patients have provided observations at the systems level that often parallel findings in animals. The best outcomes are associated with the greatest return toward the normal state of brain functional organization. Reorganization of surviving central nervous system (CNS) elements supports behavioral recovery, with several cardinal patterns of brain reorganization apparent as contributory. A number of therapies are in development to improve patient outcomes by promoting repair after stroke, and likely many will be useful in other forms of CNS injury such as multiple sclerosis (MS), spinal cord injury (SCI), and traumatic brain injury (TBI). The optimal methods to prescribe such therapies requires further study, with anatomical, functional, and behavioral measures of brain state, as well as measures of injury, likely proving useful toward this goal.

## STROKE

### Spontaneous Behavioral Recovery After Stroke in Humans

In the weeks following a stroke, human subjects generally display some degree of spontaneous behavioral recovery. Considerable variability exists, however (1). Key principles identified to date are that most spontaneous recovery tends to occur within the first 3 months after stroke onset, cognitive deficits are more likely than motor deficits to show spontaneous gains beyond these 3 months (2–5); stroke survivors with more mild deficits achieve recovery quicker than those with more severe deficits (6–10); and that different patterns of recovery can exist across different neurological domains within the same patient (11,12). Because of the differences in the rate and extent of recovery across neurological domains, restorative stroke trials might need to use behavioral outcome measures that focus on a single neurological domain rather than the global behavioral scales employed in acute stroke studies (12).

### Insights from Animal Studies

Studies in animal models of stroke have provided insight into the events underlying spontaneous behavioral recovery after stroke. These studies have particular value because animal studies are able to provide insight at the molecular and cellular levels.

A unilateral infarct is associated with a number of growth- and repair-related molecular events. In many cases, unilateral injury incites a bilateral response (Table 81-1). These have been reviewed in detail elsewhere (13–19). These include structural changes in axons, dendrites, and synapses; increased activation and migration of endogenous neural stems; plus changes in extracellular matrix, glia, and angiogenesis. The brain becomes excitable, for example, showing increased *N*-methyl *D*-aspartate (NMDA) receptor binding and gamma-aminobutyric acid (GABA) receptor down-regulation (20,21). Cell cycle proteins and growth factors increase to levels far above the normal level for the adult mammalian brain (22–25). Many of these events are most pronounced in the peri-infarct area.

Insights have also come from studies of cortical representational maps. Nudo et al. (26), in a landmark study, described changes in the hand motor map after stroke in sub-human primates. These authors found that hand motor training after stroke was associated with expansion of the motor cortex hand representation (Fig. 81-1). This reorganization was later found to be related to local synaptogenesis (27). Similar findings have been described in primary sensory cortex (28). Other influences on cortical representational maps, such as demographics (29–31), injury (32–35), medications (36), experience (17), and environment (26,37–40), have also been described.

Magnetic resonance imaging (MRI) studies in animals have also provided insights into the basis of behavioral recovery from stroke. These are of particular value: they examine changes in representational maps noninvasively, and furthermore the metrics extracted can be very similar to the metrics reported in human studies; such direct comparisons might be very useful for effective translation of therapeutic advances. For example, changes in connectivity between sensorimotor cortex and deep gray matter structures in rats subjected to middle cerebral artery (MCA) stroke (41) are similar to findings in human stroke patients (42). Also, serial functional MRI (fMRI) studies examining rat upper limb have described a shift in laterality of activation after stroke such that early

**TABLE 81.1** Molecular and Cellular Repair-Related Changes After Stroke

Inflammation
Increased growth factors and growth-associated proteins
Increased cell cycle proteins
Down-regulation of GABA receptors
Increased NMDA receptor binding
Hyperexcitability, with facilitation of long term potentiation
Angiogenesis
Increased synaptogenesis
Increased dendrite branching and spine density
Increased neuronal sprouting
Increased cortical thickness
Extracellular matrix remodeling

Growth- and repair-related molecular and cellular changes after a unilateral infarct in animal models. In most cases, these changes arise bilaterally. Some of these changes increase with therapeutic intervention, in parallel with enhanced behavioral gains, further supporting their importance as biological targets for promoting repair after stroke (18,407).

after stroke, brain activation during affected paw stimulation is mainly in the contralesional sensorimotor cortex. Later after stroke, activity shifts toward the prestroke (normal) pattern in the ipsilesional sensorimotor cortex (43,44). These findings are closely aligned with findings from serial fMRI exams in human subjects with stroke (45–50).

**Systems Insights from Brain Mapping Studies in Human Subjects**

The molecular measurements from animal studies are difficult to obtain in humans, though occasionally specific questions can be probed with molecular imaging methods such as positron emission tomography (PET). Information regarding the brain events underlying stroke recovery in humans can be obtained, however, from studies of brain systems via brain mapping. A number of functional neuroimaging methods have been used to this extent.

Overall, after stroke in humans, tissue function is reduced within the injured (or for deep strokes, overlying/corresponding) primary neocortex (51–53). Behaviors that rely on the dysfunctional primary cortex suffer. The best spontaneous return of behavior is associated with resolution of such reductions of cortical function. A number of compensatory brain responses also contribute to spontaneous behavioral recovery. These include increased activation in secondary areas that are normally connected to the injured zones through a distributed network, a shift in interhemispheric lateralization toward the contralesional hemisphere, and shifts in representational maps surrounding the infarcted zone. In many cases, the larger the injury or greater the deficits, the more these compensatory events are seen. These compensatory responses are tricks of the desperate, but in patients with injury-related deficits several lines of evidence suggest that often they are better present than absent. However, the best behavioral outcomes after stroke are associated with the greatest return of brain function toward the normal state of organization (49,53–57). These findings take on particular importance when it is realized that the same events that support

**FIGURE 81-1.** Serial findings using intracortical microstimulation mapping in subhuman primates **(A)** before experimental stroke and **(B)** after stroke plus a program of rehabilitative training focused on hand. The rehab training prevented loss of hand territory adjacent to the infarct, when compared to animals not receiving this training. In some instances, the hand representations expanded into regions formerly occupied by representations of the elbow and shoulder. This study demonstrated that rehabilitative training can shape subsequent reorganization in the adjacent intact cortex, and suggested that the undamaged motor cortex may play an important role in motor recovery. The long thin arrows point to regions of undamaged cortex in which digit representations have invaded regions formerly occupied by representations of the elbow and shoulder.

spontaneous recovery are likely those to be measured to assist studies aiming to therapeutically improve recovery (58).

### Stroke Injury Reduces Cortical Activity Locally

When a stroke injures primary cortex and/or its underlying white matter (and sometimes corresponding basal ganglia), cortical function is reduced initially, increasing over time (45–47,49,56,59). Thus, several lines of evidence suggest that final behavioral outcome at the end of the stroke recovery period is related to the degree of activity in primary cortex underlying the behavior under study (60). For example, a study of patients with stroke who had reached a plateau in motor recovery found that the volume of primary sensorimotor cortex activation in the ipsilesional hemisphere during affected hand movement was related to the level of behavioral recovery (53). Similar findings have also been described in language (49,55,61–63) and right hemisphere attentional networks (56). Consistent with this, transcranial magnetic stimulation (TMS) studies of motor cortex and its efferents after stroke have generally found that cortical motor maps are smaller and corticospinal tract physiological integrity is reduced in proportion to severity of clinical deficits (64).

Viable cortical regions that surround an infarct might have special importance to repair and recovery. In animals, this peri-infarct zone often shows the greatest levels of growth-related molecular changes after stroke (14,18,26,38,65–76). Furthermore, amplification of peri-infarct repair-related events in animals by a therapeutic intervention has been associated with improved behavioral outcome (69,71,77,78). In humans, the volume of threatened but surviving peri-infarct tissue is directly related to final clinical outcome (79,80). Brain mapping studies in humans with chronic stroke have often noted peri-infarct activity (55,81–92), though the T2\*-weighted MRI signal used to measure brain activation with fMRI is itself altered in the peri-infarct zone, perhaps due to glial scarring (87). This observation complicates application of fMRI to the study of peri-infarct regions in patients with cortical stroke.

### Stroke Injury Incites Increased Cortical Activity at Distant Sites

Three main forms of reorganization at sites distant from stroke have been described: (a) increased activity in brain regions distant from, but connected to, the stroke zone; (b) increased activity in the contralesional hemisphere, which reduces the extent to which interhemispheric balance is lateralized; and (c) somatotopic shifts within intact cortical regions. Each has been associated with behavioral improvement after stroke.

The first of these is increased activation within cortical areas that, prior to stroke, comprise a distributed network (49,63,81,83,93–102). This has been described in many studies, indeed since the first poststroke functional imaging study by Brion et al. (103). Reaction across a distributed network has been reported across many neurological domains including motor, language, attention, and visual functions.

A second form of reaction to stroke is reduced laterality of brain activity (61,81,93–96). Reduced laterality is a cardinal pattern of brain response to injury, having also been described

in other neurological contexts such as epilepsy (104), TBI (105), primary progressive aphasia (106), and MS (107). Note that the degree of brain insult needed to incite reduced laterality might be much lower than previously appreciated (108,109).

The exact function served by increased contralesional activity after stroke remains to be clarified. To some extent, this can be seen as simply a contralesional example of increased brain activation at sites distant from stroke. Another interpretation is that this is a passive event, reflecting a reduced interhemispheric inhibition resulting from the stroke (110–116). Changes in interhemispheric inhibition are the focus of much discussion (114), and possibly of therapeutic value (117–119), though the significance of such findings might differ across patient subgroups (120). Another hypothesis is that the contralesional hemisphere assumes functions that were previously based in the ipsilesional hemisphere. However, the data do not support this, at least not directly and completely. For example, stimulating contralesional motor cortex with TMS does not result in movement of the affected hand (121), and indeed might indicate greater pathology if such a response is seen (122,123). Contralesional hemisphere functions might be more substantial when stroke is prenatal (124).

A third compensatory response to focal injury is reorganization of somatotopic maps. Such maps are normally present in multiple primary cortices including motor, sensory, auditory, and visual cortex, and such somatotopic organization also exists in white matter, basal ganglia, secondary neocortex, and the hemisphere ipsilateral to movement (125–130). Nonhuman primate studies have provided rich characterization of cortical map changes after ischemic injury, providing insight into the effects of rehabilitation as well as infarct size, and also describing novel axonal projections that can arise in this context (13,26,37,38,131,132). This process has been less studied in humans after a stroke, where most, but not all (83,133,134), investigations have focused on the motor system. In the motor system, the large scale features of motor cortex somatotopy that are normally present (135) are preserved though occasional exceptions have been described (136). A shift of the motor cortex hand representation after stroke in the dorsal (137), ventral (53,94,98,136,138), or posterior (82,136,139–142) direction has been reported. Sites assuming such a shift in brain activation can demonstrate increased cortical thickness (134).

The motor cortex map relationships between face and hand may be among the most plastic in the brain, a suggestion that is supported by reports of invasion of hand motor representation into face motor area (53,98,136,138,143–145) and face into hand (146,147), in a variety of settings, first described after stroke by Weiller et al. (94). This process might reflect survival of distinct subsets of corticospinal tract fibers (128,148) that have key axonal connections between hand and face areas (149), and so could theoretically represent an approach to identify a biologically distinct subgroup of stroke patients in whom a particular therapy (one that encourages a ventral hand map shift) might be most likely to succeed (Fig. 81-2).

These forms of poststroke increased activation have certain principles in common. These changes are not epiphenomena,

**FIGURE 81-2.** **A:** Weiller et al. (94) found that in patients with good recovery after deep stroke, the hand map on motor cortex extended ventrally (*white arrow*), toward the face area. **B:** Zemke et al. (53) found that this process was associated with a better behavioral outcome after stroke. White arrow indicates the central sulcus.

as suggested by virtual lesion (150–154) and other approaches (155–157), but rather directly contribute to spontaneous behavioral recovery. Increased activity in distant areas (46,98,158) and reduced laterality (45,48,49,54,136,159,160) are time-dependent, increasing in the early weeks after stroke and generally declining thereafter. This decline is greater among subjects with better behavioral outcome, as the degree of persistently increased activity in both instances is generally highest in those with the poorest behavioral outcome (54,136,161). However, note that persistent, increased reorganization is not always helpful, as persistence of poststroke plasticity can be associated with induction of epilepsy (162) or chronic pain (163).

### Diaschisis

The changes arising in areas distant from injury might in part be related to diaschisis or its resolution. Diaschisis refers to reduced activity, typically measured in terms of blood flow and/or metabolism, in uninjured brain areas that have rich connections with injured brain areas (164–166). Some data suggest that behavioral recovery is facilitated by the resolution of diaschisis, that is, restitution of brain activity in these uninjured areas that are distant from, but connected to, the site of infarct (50,167,168). The optimal method for defining, and thus for measuring, diaschisis remains unclear.

### Time Window Influences Application of Restorative Therapies after Stroke

The time window that defines a restorative therapy likely varies according to the therapy and biological target. The biological targets for restorative agents vary over time, with brain levels spontaneously rising then falling dramatically in the weeks following a stroke. Some models have broken down poststroke brain changes into three epochs (160,169,170) that overlap at least in part: (a) acute injury, taking place in the initial hours after a stroke; (b) repair, starting in the first days after stroke onset and lasting several weeks. This is a golden period for initiating exogenous restorative therapies, as the greatest degree of spontaneous behavioral recovery is seen, and endogenous repair-related events (see Table 81-1)

reach peak levels (Fig. 81-3). Note that exogenous therapies, from pharmacotherapies to behavioral interventions, must be examined in a two-tailed manner, as each can be deleterious

**FIGURE 81-3.** The timing of rehab influences its efficacy (4). Rats with an experimental stroke received 5 weeks of enriched rehab beginning 5 (“ER5”), 14 (“ER14”), or 30 (“ER30”) days after stroke onset. The x-axis depicts time; prior to stroke, at the end of training (“Training”), groups were similar. After stroke, but before enriched rehab, animals with MCA occlusion all showed a major drop in the number of pellets eaten, while control animals (which had either sham surgery or a very small stroke) showed little change. When examined 35 days after initiation of enriched rehab, the program initiated early after stroke showed significantly more gains than a program initiated late after stroke. However, the limited human data available on application of intensive therapy very early after stroke might be deleterious (5); clearly, further studies are needed.

**TABLE 81.2** Variables Influencing Stroke Recovery

Infarct size	Infarct location
Prestroke medical co-morbidities	Prestroke disability
Prestroke experience and education	Age
Severity of initial stroke deficits	Breadth of stroke deficits
Acute stroke interventions	Medications during stroke recovery period
Amount of poststroke therapy	Type(s) of poststroke therapy
Medical complications poststroke	Socioeconomic status
Depression	Caregiver status
Genetics	

as well as potentially helpful, as discussed below; (c) a plateau, starting weeks-months after stroke, and representing a stable but still modifiable chronic phase. This third phase might have two temporal components (98): one representing the beginning of the chronic phase, with associated loss of treatment windows from phase 2, and the other arising many months-years after stroke onset, associated with late changes and complications. Late changes and complications of a “late plateau” epoch include new dystonias, cognitive/affective changes, and spasticity/contracture.

### Other Factors Influencing Recovery

A number of general factors can influence outcome after stroke (47,85,148,166,169,171–190) (Table 81-2). The quality and intensity of behavioral experience during the weeks-months following a stroke, and the environment in which this experience takes place, are well established as having a major influence on behavioral outcome after stroke (39,191–200). The nature of the physical and social environment also influences the brain, in health (201) and after stroke (202). Genetic factors might also be important (203,204). Note that a number of factors can also *reduce* behavioral recovery after stroke. One example is drugs such as neuroleptics or antiepileptics (205–208). Other drugs, such as benzodiazepines, can induce an amnesic state: a patient can have poststroke deficits, recover spontaneously, then have the deficits reemerge years later upon administration of certain drugs (209–212). The brain events that support behavioral recovery appear to have a vulnerability (213) that lasts a lifetime.

### Restorative Therapies

Restorative therapies aim to promote behavioral recovery after stroke. Numerous therapies, devices, and interventions for modifying function after stroke have been evaluated and are considered below.

### Small Molecules

Many chemical events in the poststroke brain are relevant to repair. Not surprisingly, a number of small molecules have been examined as potential therapies in this context. The mechanism for some of these small molecules revolves around direct manipulation of a specific neurotransmitter axis, such as increasing tone at serotonergic (214,215) or monoaminergic (216–218) receptors. Results with the latter example, such as with amphetamine and related drugs (219–225), have been mixed. Other small molecule approaches have been examined (226–233), including immune-based approaches (234).

### Growth Factors

Growth factors play an important role in the development and spontaneous brain remodeling and thus, might have great promise as therapies to improve function after stroke. A wide range of potential mechanisms exist, including promoting activity-dependent synaptic competition, long-term potentiation, facilitating key protein synthesis and synaptic transmission, and more. Several positive preclinical studies have been published (72,235,236), including those employing a hematopoietic growth factor (237–239). Kolb et al. (240) found that sequential administration of epidermal growth factor and erythropoietin to rats with experimental infarct reduced deficits, in some cases when treatment was initiated 7 days after stroke onset.

In most cases, these growth factors have been initiated 24 hours or longer after stroke onset in a rodent model of experimental stroke, and found to improve long-term behavioral outcome. This long therapeutic time window, the large number of examples of successful preclinical studies, the use of compounds that are endogenous to humans, and reliance on compounds that in many cases have a long history of safe application in humans are all factors that predict future successful application of growth factors to restoring function after stroke in humans.

For large molecules such as growth factors, access to the brain might prove to be a significant challenge. One potential solution to this involves the use of a “trojan horse” approach (241).

### Cell-Based Therapies

A number of forms of exogenous cells, including induced pluripotent (242,243) and embryonic stem cells (244,245), have been examined in preclinical stroke models (246,247). Mobilization of endothelial progenitor cells (248) might also help repair after stroke (249). Limited data are available on treatment of human subjects with stroke using exogenous cells (246,247). The safety and feasibility of intracerebral transplantation of cultured neuronal cells in humans were established in two trials of Layton BioScience-neurons (250,251), with at best modest results. A small trial in human patients with subacute stroke found intravenous mesenchymal stromal cell (MSC, also referred to as marrow stromal cell) infusion to be safe and possibly effective for reducing disability (252). MSC can be prepared autologously, eliminating the need

for immunosuppression, and might have a therapeutic time window of up to 1 month poststroke (253). MSC might also prove useful as a conduit for therapies targeting specific genes (254–257). A number of issues require addressing whatever the cell used, such as establishing biological identity, activity, purity, and stability over time.

### Electromagnetic Stimulation

The brain is an electrical organ. Electromagnetic stimulation has thus been used to modulate a number of brain functions; indeed a brain-wide form of electromagnetic stimulation, electroconvulsive therapy, remains the gold standard for the treatment of major depression (258). Several forms of electromagnetic intervention are under evaluation to improve function after stroke, though in most cases studies are at an early phase. One such form of stimulation is repetitive TMS, which, depending on the number of stimuli per second, can have inhibitory or excitatory effects on cortical activity (259). As such, goals can include increased activity in ipsilesional cortical regions that are underactive (260–262), or decreased activity in contralesional cortical regions that are overactive and a source of potentially harmful inhibition (118,119). Transcranial direct current stimulation has also shown promise in initial studies, and might be less focal in its brain effects (263). Epidural motor cortex stimulation might also improve motor function after stroke (264), though a phase III study in 164 patients with chronic stroke found that the effects on motor status of epidural motor cortex stimulation plus rehabilitation therapy did not significantly differ from rehabilitation therapy alone (265).

### Device-Based Therapies

Numerous devices are under study to improve function after stroke, some employed external to the body and others surgically internalized. Some devices aim to substitute for the injured CNS, such as via a brain-computer interface (266,267). For others, such as via a laser-based device (268), functional electrical stimulation (269), neuroprosthetic, and robotic devices (270), the goal is to improve function in surviving CNS elements. Electrical stimulation and neuroprostheses are further discussed in Chapters 71 and 48, respectively. A number of different robotic devices have been examined (271–275). These devices have been largely focused on motor function, where mild-moderate gains have been documented. Robotic therapy offers potential advantages in that robotic devices can be active without fatigue for very long time periods, perform in a consistent and precise manner, can be programmed, have the capacity to measure a range of behaviors, and are enabled for telerehabilitation. Robotic therapy is further discussed in Chapter 83. Combination approaches employing a robotic therapy alongside a second restorative therapy such as a drug or neuromuscular stimulation have been less studied but might prove fruitful.

### Task-Oriented and Repetitive Training-Based Interventions

Interventions based on task repetition are important to the repair process for at least two reasons: first, behavioral

experience influences effectiveness of other interventions such as pharmacological therapy. Second, task-oriented and repetitive training-based interventions might have significant value as the main therapy of interest (276–278). A number of forms of therapy have been studied, with uncertain results at this time as to which is best. Cognitive-based strategies, such as those based on motor imagery or action observation, have shown promise (197,279–287). Interventions in the motor system have included bilateral training (288), use of a gravity-reduced environment (289), EMG trigger coupling (290), incorporating passive movement (291), or manipulating movement speed (292). The structure (293) and intensity (192,196) of the training program can influence extent of gains.

One such therapy of note is constraint-induced movement therapy, which is based on overcoming learned nonuse of the affected hand after stroke (294). Constraint-induced movement therapy has the nonaffected hand restrained while the affected hand undergoes an intense course of therapy. A recent phase III trial (295) found that 2 weeks of this therapy produced gains (295) that remained significant 2 years (296) after the end of the intervention (Fig. 81-4). Modified forms of this therapy might increase the fraction of chronic stroke patients who are eligible (290). In addition, studies are examining this approach in other neurological domains such as language (297). An important question is the percentage of patients who can derive gain from this and other task-oriented and repetitive training-based interventions.

**FIGURE 81-4.** Therapy can produce significant, enduring gains among patients in the chronic phase of stroke, from the EXCITE trial, a phase III clinical stroke trial (6). Wolf et al. randomized 222 patients with moderate deficits due to a first ischemic or hemorrhagic stroke in the prior 3 to 9 months to either usual care or to 2 weeks of constraint induced therapy. These authors found significant gains in several measures, such as the amount of arm use presented in this figure, a full year following the end of therapy. Furthermore, follow-up exam 2 years after end of therapy also found significant retention of gains (7).

Key questions remain. When is the goal to simply provide a return of function via any means versus when is the goal to precisely restore CNS operations to a prestroke state? Indeed, disentangling behavioral compensation from true recovery of the specific behavior measured as an endpoint (298–301) might be important to some studies. What is the optimal time for safe and effective initiation? Indeed, application of intensive therapy very early after stroke might be deleterious (302,303). How extensive will concomitant experience and behavioral shaping need to be? How will the target population be defined? Some of these questions might be best answered by incorporating studies of brain injury and function into therapeutic decision making.

### Utility of Brain Mapping Data for Restorative Therapy Clinical Trials After Stroke

Clinical stroke trials often enroll patients based on behavioral entry criteria. However, behavioral performance can arise on the basis of many different neurobiological states, only some of which are likely to respond to restorative therapy. Several studies suggest that human brain mapping can provide additional insights useful for optimal implementation of restorative therapies. By providing measures of injury and brain functional state, data from fMRI, PET, TMS, magnetoencephalography, electroencephalography, and other methods might be of value to clinical trials.

There are several functions that functional neuroimaging measures might play. One might be to guide particular details of a restorative intervention. If a therapy achieves its effect by targeting a specific functional brain region, such as the hand motor area, anatomical localization might be insufficient because localization of a specific function in the brain often has an inconsistent relationship with brain anatomy (304–309). Serial measurement of brain function might also guide therapy dose or duration (310,311). This approach has been demonstrated in clinical (312,313) and research (264,314) settings. A second role for functional neuroimaging measures might be to guide dose of therapy, for example, via measurement of fMRI laterality measurements (310) or motor-evoked potential by TMS (311).

An additional potential value of functional neuroimaging methods is to serve as entry criteria. Having a measure of CNS functional status and injury might assist usual behavioral and demographic measures (191,196) to identify patients most likely to respond to a given intervention. Functional measures of brain state have been incorporated into early phase restorative stroke trials and found to predict response to therapy (310,311,315,316). A recent study by Stinear et al. (317) achieved good success at predicting arm motor gains from therapy using measures of demographics, CNS function, and injury. This model, and so many others, requires validation and further investigation, for example, of clinometrics. However, likely some measures beyond those obtainable at the bedside will likely prove useful for optimal prescription of restorative therapies after stroke.

Functional neuroimaging measures might also one day serve as surrogate endpoints in the evaluation of restorative therapies. Surrogate markers can be of considerable value to

early phase trials. A proof of principle functional neuroimaging study in a small target population could be very useful when considering proceeding to a late phase trial (318). However, important concerns exist in the use of functional neuroimaging measures as a surrogate endpoint for restorative stroke therapeutics. Many more studies are needed to examine the performance of such measures in this context. A number of issues, such as the extent and specificity with which a surrogate marker captures treatment effect, require examination (319,320).

### Summary

Studies in animals and humans are providing new insights into the biological basis of spontaneous recovery after stroke. On the backbone of this knowledge, a number of restorative therapies are entering human trials to promote improved outcomes. Measures of CNS injury and function might be useful toward these efforts. Further study is needed on a number of questions to optimally prescribe restorative therapies and reduce disability after stroke.

## MULTIPLE SCLEROSIS

MS is also a common source of disability, and motor deficits are also common in MS (Chapter 41). These deficits are acquired over a much longer time in MS as compared to stroke. For example, in one study of a broad range of subjects with MS, the median time to reach irreversible limited walking ability for more than 500 m without aid or rest was 8 years, to walk with unilateral support for not more than 100 m without rest was 20 years, and to walk for not more than 10 m without rest while leaning against a wall or support was 30 years (321). Upper extremity motor deficits, such as those related to ataxia and paresis, are also a common source of disability in MS (322).

Brain plasticity is an important determinant in MS over two time scales. First, steady destruction of myelin and axons over the years results in disability. During this period, reorganization of brain function can reduce the impact that such injury has on behavioral decline. Second, over weeks-months, approximately 85% of patients with MS have a relapsing, remitting course (323) in which a relapse peaks over 1 to 2 months and then improves over a similar time period. The resolution of these MS flares has been attributed to a number of brain events, such as neurological reserve and resolution of inflammatory insult (323), and a number of studies suggest that brain plasticity is also important (58). Note too that there are numerous asymptomatic brain lesions for each symptomatic one in most patients with MS, a fact that might further support the importance of brain plasticity in the maintenance of behavioral status in this condition.

Brain plasticity, thus, is likely important to motor status in MS, by minimizing the debilitating effects of MS injury accrual over the long-term period and by promoting recovery from silent or symptomatic MS flares over the short-term period. A number of studies have provided insights into the

brain events important in this regard, with substantial overlap as compared to findings in patients with stroke. This information gains importance in the current discussion because events important to maximizing behavioral status in the natural course of the disease are likely to be many of the same measures whose measurement can guide optimization of therapy-derived recovery.

fMRI studies of brain plasticity in MS have found that, early in the course of the disease, brain activation is larger and more widespread as compared to healthy controls. Later in the disease, laterality of activation is reduced (i.e., activation is more bilateral) (324–326), akin to stroke patients who have larger infarcts or greater deficits (54,136). Bilateral sensorimotor cortical regions are activated to a greater extent in the setting of MS-related white matter injury (327,328). This increased degree of bilateral organization persists to the greatest extent in subjects with persistent deficits after an acute MS relapse and returns to a normal, lateralized (i.e., contralateral-predominant) form of organization in subjects with the least degree of persistent disability (329,330). The pattern of brain activation during performance of a simple motor task in subjects recovered from stroke has been considered similar to the pattern seen in healthy subjects during performance of a complex task (81); a similar analogy has been made in subjects with MS (331).

A number of repair-based therapeutic strategies are also being explored in MS, though considerably less knowledge exists on this approach in MS as compared to in stroke. Many of these overlap with approaches described for stroke, above, such as stem cells and growth factors. Manipulation of myelin growth inhibitory molecules such as Nogo, as well as other myelin components, might also be an important avenue to promote repair in this demyelinating disease. A range of immune-based approaches, which constitute the centerpiece of acute MS therapies, might also have a role in promoting repair (332–337).

A handful of studies have examined the utility of brain mapping data for restorative therapies in patients with MS. Parry et al. (338) tested the effects of increased cholinergic tone on the pattern of fMRI activation during performance of the Stroop test, a cognitive task. At baseline, patients with MS and moderate disability had similar behavioral performance as compared to controls, but on fMRI showed increased left medial prefrontal, and decreased right frontal, activation. Treatment with the cholinesterase inhibitor rivastigmine normalized both of these fMRI abnormalities in patients, but had little effect on a small cohort of healthy control subjects. Mainiero et al. (339) found that administration of 3,4-diaminopyridine to patients with MS was associated with reduced intracortical inhibition and increased intracortical facilitation. Though no behavioral correlates were noted in relation to these physiological changes, a favorable effect on behavior would be expected by analogy (189,263,340).

## SPINAL CORD INJURY

Though SCI can be associated with a range of injury patterns, motor deficits are generally a prominent feature (Chapter 47).

At the time of discharge from initial SCI, the most frequent neurologic category is incomplete tetraplegia (31.2%), followed by complete paraplegia (28.2%), complete tetraplegia (17.5%), and incomplete paraplegia (23.1%). Less than 1% of persons experience complete neurologic recovery by hospital discharge (341).

Persons with SCI generally show modest spontaneous sensory and motor improvement in the first 3 to 6 months following injury (342,343), although significant spontaneous improvement beyond the first year post SCI is uncommon (344). Motor deficits are thus common and persistent after SCI, and these impact a number of health, quality of life, and other issues in subjects with SCI (345–347). For example, by 10 years after SCI, 68% of persons with paraplegia, and 76% of those with tetraplegia, remain unemployed (348). Concerns over sexual and bowel/bladder function are also prevalent (349).

There has been limited study of the changes in the function of the human CNS after SCI. Some studies have found a broad decrease in brain activation (350–352), particularly in primary sensorimotor cortex, whereas others have found supranormal brain activation (353). The basis for these discrepancies remains unclear but could be due to differences in age or injury pattern of the population studied, years post SCI at time of study, or the nature of the task used to probe motor system function, some uncovering deficient processing and others emphasizing supranormal efforts to compensate (351,354). A commonly described feature is a change in somatotopic organization within primary sensorimotor cortex, with representation of suprasacral body regions expanding at the expense of infralacral body regions (102,355–358). Spontaneous changes in laterality, so prominent in studies of stroke or MS, as above, are generally not prominent after SCI, perhaps due in part to the fact that injury typically affects the CNS bilaterally or perhaps due in part to the fact that SCI spares brain commissural fibers whose integrity helps maintain normal hemispheric balance. As such, a laterality index is unlikely to be a useful variable in brain mapping studies of subjects with SCI. Widespread abnormalities in the limbic system have also been described (359,360), the full impact of which has yet to be appreciated. The temporal sequence of brain changes after CNS are just beginning to be understood (351). Also, the direct study of spinal cord function and plasticity at the level of the spinal cord is an emerging approach that might provide novel insights after SCI and after other forms of SCI (361,362).

A small number of studies have examined changes in CNS function in relation to therapy after SCI. Wolfe et al. (363) found that 4-diaminopyridine can improve central conduction time in subjects with SCI. Winchester et al. (364) studied body weight supported treadmill training in four patients with motor incomplete SCI. These authors compared fMRI during attempted unilateral foot and toe movement before versus after training. This therapy was associated with increased activation within several bilateral areas, including primary sensorimotor cortex and cerebellum, though to a variable extent. The authors observed that, although all participants demonstrated a change in the blood-oxygen level–dependent signal following training, only those patients

who demonstrated a substantial increase in activation of the cerebellum demonstrated an improvement in their ability to walk over ground, suggesting that this measure in this brain region, at least when examined using this task during fMRI, might be useful as a biological marker of successful treatment effect. A small study suggests that gains from treadmill training correlate with improvements in motor system physiology (365). Similarly, a case report motor cortex hand map expansion in relation to gains from hand sensorimotor physiotherapy (366), though this result was not found in a larger study (367). These initial findings anticipate that many of the principles under discussion for use of brain mapping to improve physiotherapy effects in trials of recovery after stroke, such as use of physiology or brain map measures as entry criteria or as treatment biomarkers, might also pertain to SCI.

Another form of intervention that has been evaluated after SCI is motor imagery. Motor imagery normally activates many of the same brain regions as motor execution, and has been associated with improvements in motor performance (279,368). The effects of 1 week of motor imagery training to tongue and to foot were evaluated in ten subjects with chronic, complete tetraplegia/paraplegia plus ten healthy controls (369). The behavioral outcome measure was speed of performance of a complex sequence. Motor imagery training was associated with a significant improvement in this behavior in a nonparalyzed muscle group, the tongue, for both groups. In both the healthy controls and the subjects with SCI, serial fMRI scanning (before vs. after training) during attempted right foot movement was associated with increased fMRI activation in left putamen, an area associated with motor learning, despite foot movements being present in controls and absent in subjects with SCI. Training effects on brain plasticity can thus be measured independent of behavior effects, a finding that might be important for designing biological markers in trials targeting severely disabled patient populations. Note that this fMRI change was absent in a second healthy control group serially imaged without training. The main conclusion from this study is that motor imagery training improves brain function whether or not sensorimotor function is present in the trained limb. An additional conclusion is that motor imagery, by virtue of its favorable effects on brain motor system organization, might have value as an adjunct motor restorative therapy. Another key point from this study is that brain plasticity related to plegic limbs can be studied in subjects with chronic SCI. The above study examined, as a first step, the effects of a pure motor imagery intervention, but, as with subjects with stroke, motor imagery might have its greatest effect when directly combined with physiotherapy interventions.

## TRAUMATIC BRAIN INJURY

TBI is a common, heterogenous condition that is the source of much human suffering. Patients can present with wide-ranging impairments, including cognitive, visual, and motor. Despite

a number of advances in neurorehabilitation, substantial morbidity and mortality remain (370). TBI shares some clinical features of other forms of CNS injury. For example, predictors of outcome after TBI, such as severity of initial deficits, are similar to those described in other forms of CNS injury, though social aspects may play a larger role in TBI (371).

Treatment of TBI has been reviewed elsewhere (372,373). In the more chronic phase, physiotherapy regimens targeting TBI may not be as developed as with other conditions (374). More intensive rehabilitation programs are associated with earlier function gains (375,376). There have been limited advances in therapies that promote brain repair after TBI (377), with relatively few studies examining restorative medications in the setting of human TBI (375). Small studies suggest that some of the compounds potentially useful for promoting brain repair after stroke might have utility after TBI (378–381), possibly including brain stimulation (382), cognitive rehabilitation (383), and progesterone (384). Spontaneous increases in growth factor levels that have been observed after TBI might indicate a therapeutic role for this family of restorative therapies (22,385). Cellular therapies might also have promise in reducing disability after TBI (386,387).

Brain imaging is providing new insights into the pathophysiology of TBI effects as well as of the brain repair that arises secondarily (388). Diffusion tensor imaging (DTI) measures injury, particularly in the white matter. DTI sometimes discloses injury that was completely inapparent with standard anatomical MRI scanning (389,390), or discloses evidence of repair (391). fMRI provides information about function that, as with stroke (392), sometimes vastly exceeds what can be determined with behavioral exam (393) or anatomical imaging (394). Insights with fMRI (395–398) and other functional neuroimaging methods (399–402) extend across brain functional systems as well as injury severities (401,403). Functional imaging studies of TBI have been criticized for lack of protocol standardization (404), a concern common to study of many neurological conditions (405).

An improved understanding of the pathophysiology of TBI will be useful to better define and target repair-related processes (404). In parallel, a need exists for advances in functional neuroimaging. Such advances should permit continued growth (406) in the ability to use measures of brain plasticity in humans to improve application of restorative therapies to reduce disability after TBI.

## SUMMARY

The CNS possesses innate responses to injury. Increased attention is being paid to these. The result is a better understanding of CNS repair in humans. A wide range of therapies are under investigation with the aim being to promote CNS repair. Together, these advances anticipate regular use of restorative therapies to promote CNS repair and reduce disability in patients with stroke, MS, SCI, TBI, and other neurological conditions.

# Regenerative Medicine: Implications in Rehabilitation

## INTRODUCTION

An innovative interdisciplinary scientific field, termed *regenerative medicine*, focuses on new approaches to repairing and replacing cells, tissues, and organs and may involve the use of gene therapy (1–6). Derived from the fields of biomedical engineering, developmental biology, nanotechnology, physiology, molecular and cellular biology, and surgery, regenerative medicine holds new promise for previously incurable conditions. Potentially, any disease or condition (acquired or genetic) that results in damaged, failing, or malfunctioning tissue may be amenable to regenerative medicine technologies. These technologies fall into two general categories (Fig. 82-1): (a) a focus on growing tissues and organs *in vitro* (i.e., tissue engineering) and subsequently implanting them into the patient; and (b) a focus to fully leverage the host's regenerative *in vivo* capacity using cellular and/or gene therapies. This review concentrates on the latter approach in regenerative medicine.

In 2004, The Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) warned that failure to address the severe shortage of organs could have ominous consequences for the American population. There is about one death every 30 seconds from organ failure, and complications and rejection of transplanted organs pose significant problems. The United Network for Organ Sharing (UNOS), which maintains a database on transplantation in the United States, reported that approximately 29,000 transplants were performed annually in 2006 and 2007. However, by mid-2008 the number of Americans on waiting lists for donated organs grew to nearly 100,000. These facts point to the importance of developing new therapeutic approaches for this huge unmet medical need. In this chapter, we describe just a few of the new approaches that the emerging field of regenerative medicine uses to address this need for organ and tissue replacement.

## Cell Therapy: Regenerating Damaged Tissues *In Vivo*

Diseased tissue may be regenerated *in vivo* by transplantation of healthy cells that are able to replicate extensively. Progenitor and stem cells have this intrinsic ability, and are used in regenerative medicine to enhance or restore damaged tissue. According to data from the Centers for Disease Control, as many as 1 million Americans will die every year from disease

that, in the future, may be treatable with tissues derived from stem cells (7). Diseases that might benefit from stem cell-based therapies include diabetes, heart disease, cerebrovascular disease, liver and renal failure, spinal cord injuries, and Parkinson's disease. In the following section, we describe the classes of cells available for regenerative techniques and describe research advances using these cells in selected clinical conditions commonly encountered by rehabilitation clinicians.

## Adult Stem Cells and Tissue Progenitor Cells

Adult stem cells are defined as any stem cell population that corresponds to a point in development subsequent to the inner cell mass (ICM), or possibly the slightly later epiblast, of embryos at the blastocyst stage, prior to gastrulation. In other words, adult stem cells are usually defined as stem cells found at any point in development beyond the pluripotent cells of early embryos. Adult stem cells are relatively abundant during fetal development and persist in tissues throughout adult life. Much of our current understanding of stem and progenitor cell biology derives from studies of a particular class of adult stem cells, namely those of the hematopoietic (blood forming) system. In fact, the therapeutic use of adult stem cells dates back to the first bone marrow transplant in 1956 (8). Early suggestions supporting the existence of cells that are capable of reconstituting the blood system came from experience with persons exposed to lethal doses of radiation during World War II. In the early 1960s, James Till and Ernest McCulloch in Toronto, Canada, found evidence for a specific subpopulation of cells in the bone marrow that could restore hematopoiesis after transplantation into irradiated mice. In the spleens of recipient animals, they observed large colonies and showed that these arose as clones from individual stem cells in the donor marrow that both could replicate to generate more stem cells and could give rise to multiple types of mature, differentiated blood cells (9,10). These two characteristics, termed self-renewal and multipotency, remain generally accepted as the defining features of stem cells. In the most complete demonstration of these properties, it has been shown that one hematopoietic stem cell has the capacity to completely repopulate both the lymphoid and myeloid blood cells of a lethally irradiated mouse and that single stem cells from such rescued animals can in turn reconstitute additional irradiated hosts over multiple sequential passages (11,12).

**FIGURE 82-1.** Regenerative medicine technologies.

Human hematopoietic stem cells also have been characterized in detail and have similar properties to those in mice (13). They can be enriched using antibodies to surface markers such as CD34 and CD133 and can reconstitute the bone marrow and spleen of irradiated mice (severely immunodeficient mutant strains that do not reject human cells). In addition to bone marrow, umbilical cord blood has proven to be a valuable source of hematopoietic stem cells for therapeutic applications (14,15).

As in the bone marrow, the presence of stem cells in the intestinal mucosa was inferred initially from studies of recovery from radiation damage (16). Labeling experiments showed clearly that these stem cells are located near the base of crypts in the small and large intestines and give rise to the various mature cells of the gut. However, the intestinal stem cells have proven difficult to isolate and characterize outside of their *in vivo* niche. Recently, improved sorting and laser capture technologies have begun to facilitate the detailed phenotypic characterization of these cells (17,18).

Even under normal conditions, blood cells and intestinal epithelial cells turn over rapidly. The presence of stem cells in such adult tissues (the epidermal layer of skin serves as another example (19) has become widely accepted. The general model is that stem cells, found in special niches, serve as a self-renewing population responsible for the capacity for tissue restoration. The stem cells give rise to progenitor cells, which can still multiply many times but are unable to indefinitely self-renew or to completely reconstitute a tissue. The progenitors, in turn, are precursors of terminally differentiated cells that generally no longer divide (20,21). Operationally, it can often prove difficult to distinguish rigorously between stem and progenitor cells, as adequate long-term *in vivo* reconstitution assays are not always available. Both classes are likely to have therapeutic value.

Stem and progenitor cells also have been identified in tissues and organs in which cells normally turn over much more slowly than in the bone marrow, gut, or skin. These include skeletal muscle, liver, kidney, endothelial cells lining blood vessels, and many more (22,23). Remarkably, even specialized cell

types that for many years were believed incapable of any degree of restoration in adults, such as neurons of the central nervous system (CNS) and cardiac myocytes, now appear to have corresponding stem cells that persist throughout adult life (24,25).

### Mesenchymal Stem Cells

While many adult stem cells appear specific to the tissue or organ from which they are obtained, others are more broadly distributed and also may have less restricted differentiation potential. An example with great clinical potential is the mesenchymal stem cell (MSC), a multipotent cell that can give rise to bone, cartilage, adipocytes (fat cells), and fibroblasts. MSCs were first identified as a stromal population in the bone marrow, distinct from hematopoietic stem cells (8,10,13,14). However, similar cells have been found throughout the body, and there are now clear indications that MSCs are perivascular cells associated with blood vessels (26). An accessible, abundant source of such cells is fat tissue obtained by liposuction (27) and also from placental tissue (unpublished observations). Although termed “stem cells,” the MSCs do not display indefinite self-renewal capacity and cannot be routinely expanded in culture beyond approximately seven or eight passages. A single bone marrow donation can yield thousands of potential clinical doses of MSCs but not an unlimited supply. A subset of MSCs from bone marrow appears to have greater capacity to proliferate, perhaps “indefinitely,” and also to differentiate beyond the mesenchymal cell lineages. Verfaillie and colleagues have termed them multipotent adult progenitor cells (MAPC). The MAPCs been reported to differentiate *in vitro* into numerous tissue types and also to contribute to a wide array of adult tissues and cell types after injection into a developing embryo at the blastocyst stage (14).

Some adult stem and progenitor cell populations have proven difficult to propagate in culture. For example, despite the great effort that has been expended studying hematopoietic stem cells, there has been little success in expanding their numbers in the laboratory. Other stem cell populations, such as satellite cells of skeletal muscle, multiply substantially in culture but then show diminished regenerative capacity when transplanted *in vivo* (28). Nonetheless, some cell populations that must include adult stem and progenitor cells have been expanded sufficiently for certain clinical applications. Examples include cells from human foreskin utilized for living skin products (29) and urothelial and smooth muscle cells used in tissue-engineered constructs for bladder augmentation (30). Furthermore, certain purified stem cell populations have been grown continuously in culture for many months—at least from a practical perspective, this may be viewed as “unlimited” self-renewal. Keys for expanding a number of adult stem cells have been enrichment of rare cells using selection with antibodies to surface markers, and the use of serum-free defined medium, carefully chosen growth factors, and, in some cases, extracellular matrix components for their expansion. For example, neural stem cells can be isolated from brain tissue by positive selection for CD133 and negative selection for markers found on contaminating cell types (31). When cultured in

defined medium with fibroblast and epidermal growth factors, they grow as “neurospheres” that maintain a significant proportion of multipotent stem cells able to give rise to neurons, astrocytes, and oligodendrocytes (32,33). Recently, conditions were reported for the isolation of human hepatic stem cells, by immunoselection for the epithelial cell adhesion molecule (EpCAM), and their expansion in culture for over 150 population doublings (34–36). These cells are precursors to hepatocytes and bile duct epithelium and may have broader potential to generate other endodermal cell types. Spermatogonial stem cells provide yet another example of a growing list of adult stem cells (albeit for a germ cell fate) that can be propagated extensively in a defined medium (37).

### Embryonic Stem Cells

In contrast to adult stem cells, embryonic stem (ES) cells show essentially unlimited capacity for self-renewal in culture and should be able to give rise to any of the more than 200 cell types in the body (with the exception of certain extraembryonic cell types). The isolation of ES cells from the inner cell of blastocyst stage mouse embryos was reported in 1981 by Martin (38) and by Evans and Kaufman (39), based on many years of prior work on transformed embryonal carcinoma cells from teratocarcinoma tumors. Successful isolation of ES cells from human blastocysts was not achieved until 17 years later, by Thomson et al. (40).

ES cells have great therapeutic potential, but there are also significant barriers that must be overcome for their implementation in the clinic. ES cells are pluripotent, that is, they have the ability to form tissue representing all three embryonic germ layers—the ectoderm, mesoderm, and endoderm. Thus, the ES cell has the intrinsic ability to give rise to daughter cells that can form virtually any tissue in the body. This was demonstrated convincingly by the finding that mouse ES cells injected into developing embryos can contribute to all adult cell types, including germ cells (40,41). Human ES cells have been induced to generate representatives of all three germ layers in culture and are widely assumed to have the same degree of pluripotency as mouse ES cells.

The great plasticity of ES cells can also represent a drawback to their use, because it may prove more difficult to induce them to yield a single desired cell type exclusively than when starting with lineage-committed adult stem cells. However, significant progress has been made in the directed production of many specialized cells, or at least lineage-specific progenitors, from mouse and human ES cells (42–44). Examples include cells of neuronal, epidermal, cardiac myocytic, hematopoietic, endothelial, hepatic, endocrine pancreatic, and germ cell lineages. Another important problem that must be overcome is that undifferentiated ES cells form teratoma tumors (38–40,44). Therefore, for clinical use it will be essential to differentiate the cells quantitatively before implantation and to rigorously exclude the presence of residual stem cells. Finally, progress is being made in the derivation of human ES cells in the absence of xenogeneic feeder cells and animal proteins that may pose risks for clinical application.

The derivation and certain potential uses of human ES cell lines have engendered a significant ethical debate, especially because embryos, though donated for research, are destroyed in order to isolate the ICM (45,46). Technological advances may offer at least a partial resolution to the ethical controversy. For example, human ES lines can now be developed from single-cell biopsy at the eight-cell stage of development, without compromising the viability of the embryo, similar to a widely used procedure for prenatal genetic diagnosis (47). The development of ES-like cell lines by reprogramming of normal adult cells ultimately may put the debate to rest by providing pluripotent cells entirely without the use of donated embryos or oocytes (see below).

### Cells Derived From Somatic Cell Nuclear Transfer

Somatic cell nuclear transfer (SCNT) involves the removal of an oocyte nucleus in culture, followed by its replacement with a nucleus derived from a somatic cell obtained from a patient. Activation with chemicals or electricity stimulates cell division up to the blastocyst stage, at which time the ICM is isolated and cultured, resulting in ES cells genetically identical to the patient. In animal studies, nuclear transferred ES cells derived from mouse fibroblasts, lymphocytes, and olfactory neurons are pluripotent and can generate live pups, showing the same developmental potential as fertilized blastocysts (48–50). The resulting ES cells are perfectly matched to the patient's immune system.

Although promising, SCNT has certain limitations that require further improvement before clinical application. Animal studies have shown that blastocysts generated from SCNT and implanted into a uterus can produce an infant clone of the donor. In 1997, for example, a sheep named Dolly was derived from an adult somatic cell using SCNT (51). This form of reproductive cloning is banned in most countries for human applications. In contrast, therapeutic cloning can generate ES cell lines whose genetic material is identical to that of their source. In therapeutic cloning, blastocysts are grown until a 100 cell-stage where ES cells can be obtained, but the blastocysts are never implanted into a uterus. However, this technique has not been shown to work in humans. Initial failures and fraudulent reports of nuclear transfer in humans reduced enthusiasm for human applications (52–54). However, it was recently reported that nonhuman primate ES cell lines were generated by SCNT of nuclei from adult skin fibroblasts (55,56).

### Cellular Reprogramming

Reprogramming is a technique that involves dedifferentiation of adult somatic cells to produce pluripotent stem cells without the use of embryos. Cells generated by reprogramming are theoretically identical to somatic cells that would not be rejected by the donor. This method also avoids nuclear transfer into oocytes. Takahashi and Yamanaka (57) were the first to report that both embryonic and adult mouse fibroblasts can be reprogrammed into an induced pluripotent state (IPS).

They identified four key genes required to bestow ES cell-like properties in fibroblasts: OCT3/4, SOX2, c-MYC, and KLF4. Reprogrammed cells were selected via drug resistance. The resultant IPS cells possessed the immortal growth characteristics of self-renewing ES cells, expressed genes specific for ES cells, and generated embryoid bodies *in vitro* and teratomas *in vivo*. When the IPS cells were injected into mouse blastocysts, they contributed to a variety of diverse cell types, demonstrating their developmental potential. It was recently reported that reprogramming by transduction of four defined factors can be done with human cells (58). Retrovirus-mediated transfection of OCT3/4, SOX2, KLF4, and c-MYC generates human IPS cells that are similar to human embryonic stem (hES) cells in terms of morphology, proliferation, gene expression, surface markers, and teratoma formation. Others (58) have shown that retroviral transduction of OCT4, SOX2, NANOG, and LIN28 could generate pluripotent stem cells without introducing any oncogenes (c-MYC) (59). An alternative approach would be to use a transient expression method, such as adenovirus-mediated system (59,60). Modified donor cells may not be necessary to generate IPS cells (60).

### Stem Cells Derived From the Amniotic Fluid and Placenta

The amniotic fluid is known to contain a heterogeneous population of cell types derived from the developing fetus (61,62). Cells from this population have been shown to differentiate into adipocytes, osteocytes, neurogenic, and endothelial cells (63–66). Importantly, a subpopulation of OCT4-positive cells have been detected in the amniotic fluid (64,67). Recently, the isolation of human and mouse amniotic fluid-derived stem (AFS) cells was reported. These cells are capable of extensive self-renewal and give rise to adipogenic, osteogenic, myogenic, endothelial, neurogenic, and hepatogenic lineages (68). In this respect, they meet a commonly accepted criterion for pluripotent stem cells.

AFS cells represent approximately 1% of the cells found in the amniotic fluid. The same cells can also be found in the placenta. These cells are immunoselected for cells that express the surface antigen *c-kit* (CD117), the receptor for stem cell factor (69). AFS cells express embryonic markers such as OCT4 and SSEA4 but not other markers of ES cells. They also express mesenchymal and/or neuronal markers such as CD29, CD44, CD73, CD90, and CD105. Clonal analyses using retrovirally marked human lines confirmed that differentiated cells of various types can be derived from a single AFS cell (68).

In addition to demonstrating that differentiated cells express lineage-specific markers, we have shown that AFS cells give rise to specialized functions (68). Cells differentiated down a neuronal pathway secreted glutamine or expressed G-protein-gated inwardly rectifying potassium channels. Cells of the hepatic lineage secreted urea and  $\alpha$ -fetoprotein, while osteogenic cells produced mineralized calcium.

The recent discovery of a stem cell population in the amniotic fluid and placenta offers a promising alternative source of

stem cells for cellular therapy. The full range of adult somatic cells that AFS cells can produce remains to be determined, but their ability to differentiate into cells of all three embryonic germ layers and their high proliferation rate are two advantages over most adult stem cell sources. AFS cells represent a new class of stem cells with properties somewhere between embryonic and adult stem cell types. However, unlike ES cells, AFS cells do not form teratomas and are easily obtained without destruction of embryos. AFS could be used for both autologous and allogeneic.

### Rehabilitation Patients and Potential Impact of Stem Cell Therapy

#### Spinal Cord Injury

A target for cellular therapy in spinal cord injury (SCI) arises from the fact that damaged neurons of the CNS are unable to self-repair after damage. Transplantation of MSCs into damaged neurons of the CNS may create an anti-inflammatory microenvironment permissive to outgrowth of the proximal axon stump (70–72). Intriguing studies on olfactory ensheathing cells, specialized glial cells that surround sensory axons in the nose, suggest that when these cells are used to reestablish previously damaged pathways, severed axons have a structural connection onto which they may regenerate (73). According to the pathway hypothesis, olfactory ensheathing cells provide a “bridge” along which nerve fibers, with limited latent growth potential, may regrow. Although functional improvement after SCI has been reported in animal models following cell transplantation (74,75), only a few clinical studies of cell therapy approaches to SCI are reported. For example, a trial of bone marrow cell transplantation into SCI patients ( $n = 35$ ) reported no safety concerns, yet the data indicated only meager functional improvements (76). Of interest, two SCI patients who received both autologous MSC transplantation and rehabilitation therapy demonstrated significant functional improvement (77). The question of how rehabilitation treatment might benefit SCI patients receiving stem cell transplantation will be an important area for future investigation.

#### Brain Injury

Improvement in neurological function was reported following MSC transplantation in brain injured rats. In one study,  $2 \times 10^6$  human MSCs were infused intravenously (78) without evidence of tissue rejection. In rat models of traumatic brain injury (79) and cerebral ischemic stroke (80,81), cell chemotaxis, or homing, was observed. Homing refers to the directional migration of cells, regulated by chemokines associated with tissue damage. The ability of stem cells to migrate to diseased/injured cells, tissues, and organs is central to therapeutic utility of MSC transplantation. MSCs are naturally home to areas of tissue damage, and thus offer an attractive source of stem cells for *in vivo* regenerative applications. The mechanisms governing the efficiency of MSC homing are the topic of a number of studies (82–84).

### Myocardial Infarction

Animal models of myocardial infarction (MI) have demonstrated migration of MSCs to the injured heart with subsequent improvement in cardiac function (85–91). A comparative study of three MSC delivery methods suggested that following MI, local endocardial injection of MSCs might be a preferred technique compared to intracoronary or intravenous infusions. Endocardial injection resulted in better engraftment of cells in damaged cardiac muscle, decreased engraftment in other tissues, and did not impair coronary blood flow (92). A clinical study of post-MI patients showed that intracoronary injection of radiolabeled autologous bone marrow cells resulted in only 1.3% to 2.6% engraftment, with much of the transplanted cells lost to the spleen and liver (93). Migration and subsequent engraftment of MSCs in the heart is mediated by homing/chemokine factors, monocyte chemoattractant protein-3 (MCP-3) (94), and SDF-1 (also known as CXCL-12) (95–97). Pretreatment of a stem cell population with these factors may enhance their migratory capacity and improve their utility in therapeutic applications. Interestingly, MSC homing and engraftment into damaged or diseased cardiac muscle does not appear to directly improve cardiac function (98,99) but rather seems to create an environment permissive for regeneration and matrix remodeling by synthesizing and secreting bioactive factors (100).

### Lung Injury

Two murine studies (101,102) indicate that MSCs, and some bone marrow–derived cells, are retained in the lungs following lung injury and that endogenous MSCs may contribute to the attenuation of pulmonary fibrosis. These observations support a theory that MSCs create regenerative microenvironments in injured tissues by secreting factors that inhibit inflammation/scarring and apoptosis and stimulate angiogenesis and mitosis (103,104). Molecular players in this process include the chemokine receptor CXCR4 (and its ligand, SDF-1) (105). Few human studies are available, but a recent review (106) suggests that the immunosuppressive and regenerative properties of MSCs used in graft-versus-host disease (107) hold promise for application in idiopathic pulmonary fibrosis in patients.

### Bone Repair

Osteogenesis imperfecta (OI) results from mutations in the gene encoding collagen I that results in defective collagen production and inadequate mineral deposition. This results in brittle, easily broken bones. Two clinical reports suggest that stem cell transplantation can be an effective treatment for OI (108,109). In these studies, children with OI were given a mild course of chemotherapy followed by allogeneic, immunomatched whole bone marrow. Clinical results showed an improvement in growth velocity of 60% to 94% of the predicted median values for age and sex-matched children, within the 6 months post infusion, whereas only 0% to 40% growth velocity occurred in the 6 months pre infusion. MSCs when used in conjunction with engineered scaffolds may be used for large bone defects resulting from fractures (110).

### Muscle Degenerative Diseases

Bone marrow stromal cells, injected locally into muscles of mdx-nude mice, indicate the tremendous potential for these cells as therapy for muscle degenerative diseases such as Duchenne muscular dystrophy (DMD) (111). Toward this goal, several criteria exist for selection of an ideal cell population (112). Among these criteria is the ability of stem cells to be introduced systemically, because in order to ameliorate the dystrophic pathology, dystrophin will be required in muscles throughout the body—particularly cardiac muscle and limb, diaphragm, and pharyngeal skeletal muscles. Furthermore, restoration of dystrophin in skeletal muscle alone may further exacerbate cardiomyopathy (113). The intra-arterial introduction of mesoangioblasts, a stem cell population associated with blood vessels, resulted in significant improvements in muscle morphology and function in dogs with severe dystrophy (114). This canine model of muscular dystrophy, termed GRMD for golden retriever muscular dystrophy, will be particularly important for preclinical trials of stem cell therapy. Of note, recent evidence suggests that perivascular cells from multiple tissues possess myogenic ability (115) (Crisan et al., 2008) (210) and also present a surface marker profile identical to MSCs. Thus pericytes, mesoangioblasts, muscle-derived stem cells (116), and MAPC (117) may all represent populations related to, or derived from, MSCs. This is clinically promising because it suggests that a cell population fulfilling the criteria (118) for effective cell therapy for muscle degenerative diseases is available from easily obtained sources such as placenta (119) and lipoaspirate (120).

### Application of Rehabilitation Techniques in Stem Cell Therapy

The translation of stem cell therapy into positive changes for medical practice is clearly dependent on an increased understanding of environmental factors controlling stem cell survival, proliferation, and participation in tissue regeneration. Methods such as gene therapy and direct growth factor injection have been investigated in the laboratory as a means to manipulate the stem cell niche. Yet, each is accompanied by drawbacks, such as cost, feasibility, and safety issues, that limit their clinical application. Toward the end of finding a more practical approach to manipulation of the microenvironment, rehabilitation strategies such as exercise and neuromuscular electrical stimulation (NMES) have been investigated as a means to optimize stem cell transplantation. It was recently shown in murine models that the addition of a treadmill running protocol following the systemic delivery of bone marrow–derived stem cells resulted in enhanced donor cell contribution to myofiber regeneration (121). These changes were evident even after just 1 week of training. In a similar study, transplanted muscle stem cells show a significantly increased myofiber engraftment in dystrophic mice following a skeletal muscle overloading protocol (122). This enhanced engraftment was directly correlated with a loading-induced increase in skeletal muscle vascularity. More importantly, increased myofiber regeneration by transplanted cells was concomitant with

an increased resistance to overloading-induced weakness of dystrophic muscle.

Functional improvements are the most important criteria for determining effectiveness of cell therapy strategies. While regenerative medicine approaches have been widely investigated for use in populations commonly seen by rehabilitation professionals, rarely have rehabilitation strategies been utilized to maximize regenerative medicine's therapeutic benefit. To realize the potential of cellular therapies for positive functional and clinically relevant outcomes, a paradigm shift may be necessary, and in the future, physical therapeutics may play a critical role in helping to fulfill regenerative medicine's clinical promise.

### Direct Gene Therapy: A Tool in Regenerative Medicine

Gene therapy is based on the insertion of a normal or corrected copy of a gene into the diseased or damaged somatic cells of the recipient. While some may argue that gene therapy *per se* does not constitute regenerative medicine, the topic is covered here with the caveat that gene therapy can be one of several tools in the regenerative medicine tool kit. Because gene therapy is not yet mainstream medicine, it is generally considered experimental with associated risks and benefits (123). There are essentially two approaches (124) to direct modification of genes to correct underlying genetic defects or diseased tissue. The first strategy involves *ex vivo* transduction of the patient's own cells in culture followed by reinjection of genetically modified cells back into the same patient. The genetically modified cells subsequently secrete the desired gene product that corrects or mitigates the disease. An advantage to this *ex vivo* approach is that the use of the patient's own *autologous* cells reduces the risk of rejection compared to transplantation of *nonautologous* donor cells. Furthermore, cells can be genetically modified using nonviral vectors. Primary, autologous cell cultures also have a low risk of malignant transformation compared with "off the shelf" established cell lines.

A more commonly used alternative strategy, *in vivo* gene transfer, involves the direct delivery of genes, usually carried by viral vectors to the patient's diseased or injured tissue. An advantage of the *in vivo* strategy is the production of the desired protein by the resident cells, without the risks of unwanted cellular alteration associated with *ex vivo* modification of cells. A disadvantage of direct *in vivo* gene transfer is the risk to the recipient of tissue rejection of the viral vector or the gene product, or both. To address immune response to viral vectors, immunosuppression can be given in conjunction with *in vivo* gene transfer. Combined use of viral vectors with nonimmunogenic preparations (such as liposomes) can address the issue of vector immune response (125).

### Gene Delivery Vectors

The major obstacles for gene transfer delivery in clinical trials are low transfer efficacy, risk of mutagenesis when using integrating (i.e., retro- and lentivirus) vectors, and immune response to either the vector or the gene product (126).

The leading viral vectors used in clinical trials are lentivirus, adeno-associated virus (AAV), and herpes simplex virus (HSV) (127). The choice of vectors used for gene delivery is strongly influenced by the type of cells targeted with gene therapy. For example, if dividing cells (like cancer cells) are targeted, then vectors that can integrate into the host genome are required to preserve the integrity of transgene replication. RNA viruses (lentiviruses and retroviruses) are typically used for integrative gene therapy in dividing cells. If nondividing terminally differentiated adult cells are targeted, then nonintegrating viral vectors are used to mediate gene transfer. Two such nonintegrating viruses, adenovirus and AAV, are most commonly used in clinical trials. These viral vectors carry genetic material that does not integrate into the host cell's genome and are not replicated at cell division.

### Gene Targeting

Nucleic acid strategies enable precise targeting of genes that regulate disease and provide an emerging class of therapeutic tools in regenerative medicine. More than 50 clinical studies have used nucleic acid "antisense" strategies in a variety of conditions, including cancer, cardiovascular disease, inflammation, and infection. One such strategy, RNA interference (RNAi), is a natural process that was first observed in plants, when RNA for pigment-producing genes was introduced into petunias to enhance color. Unexpectedly, these petunias lost nearly all of their color. The realization that these effects were mediated by dsRNA was made in *Caenorhabditis elegans* and termed RNAi by Andrew Fire and Craig Mello, recipients of a Nobel prize for this discovery. RNAi works by the following posttranscriptional mechanism: (a) Short interfering RNA (siRNA) of approximately 21 to 23 nucleotides are processed by an enzyme called Dicer and incorporated into an RNA-induced silencing complex (RISC). (b) The sense strand of double-stranded siRNA is cleaved during the formation of the RISC complex. (c) RNA helicases unwind the double-stranded siRNA, and the antisense strand guides RISC to the complementary target mRNA, which is subsequently cleaved by RISC. RNAi technology has been widely applied in research. For example, we have used RNAi to model a type of limb girdle muscular dystrophy in cultured cells (128). Others have used RNAi to model therapeutic benefit in neuromuscular diseases (129). An explosion of applications have resulted from this new technology, particularly in cancer research (130). For clinical use, RNAi meets the criteria of "targeted, less toxic" gene therapy, and will likely expand the numbers of patients who will ultimately benefit from its application (131).

### Antisense Oligonucleotides

Antisense oligonucleotides (AOs) are single-stranded segments of DNA or RNA usually 15 to 25 bp in length. These short strands of genetic material are thought to work, in part, by their interaction with target mRNA and block translation into protein by preventing normal ribosomal movement along the transcript (132). Vectorless delivery of AOs may offer one solution to vector-induced immune response. Because AOs can

correct the reading frame of abnormal dystrophin transcripts that cause muscular dystrophy, a pilot clinical trial of AO therapy in four patients with DMD was undertaken with promising results (133).

## Rehabilitation Patients and Potential Impact of Direct Gene Therapy

### Spinal Cord Injury

An explosive growth in gene therapy research aimed at treatment for SCI has occurred since the mid-1990s. A large number of different strategies have been explored (134–183). Gene silencing strategies to minimize growth inhibitory signals associated with SCI have been explored using RNAi, while most other strategies have been aimed at enhancing regeneration of injured spinal cord axons. The biggest hurdle encountered thus far is the regeneration of axons across the site of SCI. Genetically modifying cells to express neurotrophins or growth factors within the damaged spinal cord increases neuron survival, sprouting, and regeneration. Overexpression of these factors is thought to increase axon growth and possibly mitigate effects of inhibitory molecules surrounding the area of injury.

Return of motor function following injury to the spinal cord is generally poor owing to the “hostile nature” of adult spinal tissue to axonal growth. One approach to this problem is the surgical implantation of a spinal cord graft, because damaged axons can regenerate into and across different types of grafts spanning the area of injury. Use of grafts made from Schwann cells or fetal spinal cord (135) has been explored and appears to enhance the growth of axons in rats (135). Gene transfer of neurotrophic factors (79,138,146,161,162,165,168,170,184–190) has also shown promise to enhance axon growth. For example, genetically modified fibroblasts expressing neurotrophic factors, glial cell-line derived neurotrophic factor (GDNF), NT-3, NT-4/5 and brain-derived neurotrophic factor (BDNF), grafted to spinal cord lesion sites in rodents induced axonal growth and in some cases induced functional recovery after SCI (140,141,166,191–193). Marrow stromal cells transduced to oversecrete BDNF have been tested in SCI rats, but without significant motor improvement (168). The effectiveness of techniques used to deliver neurotrophic factors seems to be a rate-limiting step. To address this issue, AAV vectors have been used with some success. For example, improvement in hindlimb function was observed 16 weeks after AAV-mediated neurotrophin gene transfer in SCI rats. AAV was similarly used in rats to transduce BDNF with evidence of axonal growth of descending axons along with significant recovery of hindlimb function.

### Neurodegenerative Diseases

Gene therapy holds promise as a means to correct the underlying molecular defects that result in neurodegeneration by manipulating gene expression in targeted cells within the CNS. Both gene transfer and gene silencing (194) have been studied in animal models of neurodegenerative diseases (195) with marked improvement in pathologic and functional measures.

In the past, therapeutic gene delivery to the CNS has proven an impediment to the development of effective therapy for diseases of the motor neuron. With the discovery that AAV, when injected intramuscularly, is transported from presynaptic terminals to motor neuron nuclei in the spinal cord, came the ability to selectively target spinal motor neurons affected by motor neuron diseases. For example, intramuscular injections of AAV carrying IGF-1 prolonged the survival of the SOD-1 mouse, a preclinical model of amyotrophic lateral sclerosis (ALS) (159). SOD-1 mice injected with AAV-IGF-1, either before or after the onset of symptoms, exhibited higher muscle mass and increased motor neuron preservation compared to controls. Direct brain injections of AAV for gene delivery of the neurotrophic factors BDNF and GDNF were tested in a rat model of Huntington’s disease (196). AAV-mediated gene delivery appeared to provide neuroprotection to certain types of striatal neurons that are selectively vulnerable to degeneration following exposure to an excitatory amino acid. A line of research (197–201) has shown that neurotrophic factors offer significant neuroprotection in animal models of Huntington’s disease, thus supporting the preclinical relevance of AAV-mediated gene transfer strategy for patients with this disease. Neurotrophic factors delivered by viral vectors have been evaluated in similar models of neurodegeneration. For example, a rat model of Parkinson’s disease has been used to evaluate potential benefits of viral-mediated delivery of neurotrophic factors (202–205). *In vivo* rat experiments as early as 1998 demonstrated that viral-mediated GDNF could protect rat dopaminergic neurons from progressive degeneration (205). Clinical trials are underway to test AAV delivery of neurotrophic factors in selected Parkinson’s patients.

### Rheumatoid Arthritis

Several viral and nonviral vectors are being used for direct gene transfer or gene silencing (206) in animal models of rheumatoid arthritis (RA). Gene therapy trials for RA are underway. New vectors inducing long-term and regulated gene expression in specific tissue are under development, resulting in more efficient gene transfer using viral vectors such as AAV (124).

### Muscle Degenerative Diseases

A major obstacle for effective gene therapy in degenerative diseases of skeletal muscle is systemic delivery of vectors into diseased skeletal muscle and cardiac tissue. Both rodent and canine models have been used to develop and test intravascular approaches to efficiently transduce marker genes carried by AAV into the majority of skeletal muscle in animals, including the diaphragm and the heart (207–209). Pressurized venous infusion using vascular tourniquets or balloons allows for viral vectors to escape the intravascular space and penetrate into the surrounding skeletal muscle. A surgical technique allows for cardiac muscle transduction by placing the heart on cardiopulmonary bypass, clamping the aorta and pulmonary artery followed by AAV infusion into a cardioplegic heart at cold temperature. This method has shown unequivocal evidence of global gene expression in a significant proportion of cardiac myocytes.

## Potential Impact of Regenerative Medicine Technologies on the Practice of Rehabilitation Medicine

Given the rapid technological progress in regenerative medicine, future rehabilitation treatment paradigms may significantly shift. We have experienced such paradigm shifts in recent years with advances in trauma care. For example, rehabilitation clinicians now care for patients with previously unimaginable recovery from massive multitrauma orthopedic injuries. With continued advances in regenerative medicine, rehabilitation clinicians may similarly see a number of patients with previously unimaginable survival achieved by organs or tissues regenerated with engineered constructs. The rehabilitation needs of such patients are unknown but will certainly require a holistic multiteam approach to restore full functionality. Through advances in cell therapy, clinicians may acquire new skill sets using cell or gene therapy injections for the treatment of chronic disabling conditions. Veterinary medicine is currently experiencing a paradigm shift in this respect, with some clinicians incorporating the use of autologous stem cell injection therapy for their canine and equine patients with arthritis and lameness. Advances in the understanding of biological processes driving tissue regeneration will certainly drive the field of rehabilitation in new directions that remain to be explored.

## CONCLUSIONS

The interdisciplinary field of regenerative medicine uses stem cell and gene therapy technologies to replace or repair injured or diseased tissue *in vivo*. Stem cells and direct gene therapy have been explored in animal models and in a few clinical settings to regenerate damaged or diseased tissues in SCIs, brain injuries, MI, bone and joint diseases, and degenerative muscle diseases. The influence of rehabilitation techniques on the recipients of cellular and gene therapy are under study.

# Rehabilitation Robotics

## INTRODUCTION

Rehabilitation robotics may be organized under four major mechatronic clusters, namely, (a) robotic-assistants, (b) prosthetics, (c) orthotics, and (d) therapeutic robotics. Robotic-assistants comprise devices that perform a task in lieu of the person. Prosthetics comprises devices that substitute for limb function. Orthotics aims at augmenting weak or paralyzed limbs by supporting loads and assisting or resisting relative motion between body segments. Finally, therapeutic robotics encompasses an emerging class of interactive robots that support and enhance the clinician's task of facilitating recovery, delivering therapy, and evaluating patient progress. There are other ways to organize and characterize the scope of rehabilitation robotics. For example, another traditional way separates the devices into two broader categories: the intent to assist the patient in coping with the environment (assistive technology) and the intent to assist the clinician in delivering therapy and facilitating recovery (therapeutic technology). The first three mechatronics clusters mentioned earlier, robotic-assistants, prosthetics, and orthotics, fall under the assistive technology scope while the fourth, therapeutic robotics, falls under its namesake category. More recently, some researchers have organized rehabilitation robotics under a mixed classification system which is aggregated according to user group characteristic, to the source of inspiration for the mechatronics design, and finally according to the goal of the mechatronics system. For instance, many recent conferences are organized under three tracks, namely gerontechnology (user group characteristic), biorobotics (source of design inspiration), and neurorobotics (harness neurorecovery or neuron connectivity). It must be noted that part of the rationale for the recent spurt of neologism around rehabilitation robotics has to do not only with a sense of excitement and perceived opportunities of growth but also with the strong desire to distance itself from old labels and clearly delineate a new crossdisciplinary, biomedical and engineering endeavor.

## THE PROBLEM

There is reason for this optimistic view for the rehabilitation robotics field. The demand for rehabilitation services is significant and is expected to grow apace with the graying of the population. For instance, consider cerebral vascular accidents (CVA) or stroke: according to the World Health Organization

(WHO), every year 15M persons have a stroke, with a third of them left permanently disabled (1). We estimate that the number of persons who have survived a stroke at any given time is nearly ten times the yearly survival incidence. While there is no reliable data, one can estimate an annual need for rehabilitation services on the order of 50M patients worldwide. Of course, these figures are just "back-of-the-envelope" estimates and must be checked against accurate statistics and local variability. Nevertheless, these coarse estimates highlight the sizeable need and opportunity to deploy technologies such as robotics not only to promote recovery but also to assist a person to cope with residual impairment and disability. Robotics can revolutionize rehabilitation medicine by harnessing technology to assist, enhance, and quantify recovery and to ameliorate the quality of life and independence of the elderly and disabled. In this chapter, we focus exclusively on therapeutic robotics (for more information on assistive technology, orthotics, and prosthetics see (2,3)).

Therapeutic robots are a new class of clinical tools for evaluating patients and delivering meaningful therapy that enables an overdue transformation of rehabilitation clinics from preindustrial manual operations to technology-rich activities. Applications of robots to therapy are fairly recent, with the premier engineering journal in the field, the IEEE Transactions on Rehabilitation Engineering, coming to life only in 1992 (renamed in 2001 to IEEE Transactions on Neural Systems and Rehabilitation Engineering). In the last 10 years, the field of rehabilitation robotics has undergone vigorous growth. Borrowing an appropriate neologism, we "googled" Google Scholar with the words "rehabilitation robotics" and tracked yearly growth of academic activity in the field (Fig. 83-1). These data should be viewed with appropriate caution, particularly during the early years. But recent robust growth shows no sign of slackening and reflects a real phenomenon that is far from abating.

To keep pace with this fast-growing field is a daunting task, and our goal in this chapter is not to present a survey of the different existing devices, which would be doomed to obsolescence because of the pace of change. That task would better be achieved by tracking publications in the top journals in the field and the meta-analysis of results (4–9). Here, we attempt to highlight some basic robotic differences, present some limited outcomes employing both upper and lower extremity robotic devices, discuss some common concerns with the technology, and finally discuss potential mechanistic views of why it might actually work.

**FIGURE 83-1.** Number of hits of academic papers on rehabilitation robotics.

## DIFFERENT ROBOTS: WHAT ARE THE DIFFERENCES?

This increase in activities has resulted in a multitude of different designs, different devices, and different choices for clinicians. Rather than make an exhaustive comparison of different designs, our goal herein is to discuss the critical differences among therapy robots. However, it is very important to stress that ultimately only exhaustive clinical results can actually determine what works, what does not, what works better, when to deliver therapy during the course of the illness or recovery, and, most importantly, for whom.

### End-Effector Versus Exoskeletal Designs

The whole gamut of devices can be parsed into two broad categories of “end-effector” or “exoskeletal” designs (Fig. 83-2). Care must be exerted to understand the design trade-offs. Exoskeletal devices allow us to estimate with reasonable accuracy the kinematics of the human joints, but this advantage comes at a cost as it takes considerable time to properly adjust the lengths of the device links to each patient’s limb lengths. Note that proper collocation of the device and human joints might be necessary in some designs to prevent injury. Another advantage of an exoskeletal design is that it allows for a smaller package when therapy requires large human joint angle displacement. End-effector designs for very large human joint angle displacement require larger devices. Conversely, because the actuators (motors) are typically located at the joints of an exoskeletal device which must carry the weight of each actuator, large transmission reduction ratios are typically employed to reduce the weight of these motors, which lead to intrinsically large impedance (see below for more information). The end-effector based robots operate essentially by “handshaking”

with the patients. While there may be more uncertainty about the kinematics of patients’ limb motions, donning and doffing times are minimal with this class of devices. Furthermore, because the motors are typically mounted on the base of the end-effector robots and not carried on the robot joints, the devices can employ larger actuators with smaller transmission reduction ratios (including direct drive designs) leading to intrinsically lower impedance devices—a very important consideration to enhance robot performance and stability (see for example MIT-Manus). As a general rule, we typically consider exoskeletal designs when the human joint must rotate by more than 60 degrees (e.g., MIT’s wrist robot); otherwise we prefer end-effector designs.

### Intrinsically High Impedance Versus Low Impedance Design

Exoskeletal or end-effector designs employ motors which have not only weight and mass to be accounted for in any design but also static and viscous friction. A comparison of the ratios of energy to weight for human muscle and for an electrical motor demonstrates the impressive competence of muscles. Muscles generate two to six times more energy for the same weight (typical electrical motors 50 W/kg and muscle 300 W/kg). In many robotic devices for which weight is a critical limitation (e.g., exoskeletal robots like MIT’s Anklebot), speed-reducing transmissions are employed to increase the torque output without excessive increase in weight.\* An unintended consequence

\*From the conservation of energy, torque  $\times$  angular velocity at the motor output shaft is the same as the torque  $\times$  angular velocity at the transmission reduction output shaft (assuming no losses). Therefore, to increase torque output, we must reduce the angular velocity at the transmission reduction output shaft.

**FIGURE 83-2.** Rehabilitation robotics. **Top left** panel shows the shoulder-and-elbow MIT-Manus delivering therapy in the subacute setting. **Lower left panel** shows MIT's wrist robot delivering therapy in the chronic phase. **Right** panel shows the Anklebot, designed to address foot drop. The MIT-Manus is an end-effector type robot, while the wrist robot and the Anklebot are exoskeletal type designs.

of employing this reduction to boost the actuator torque is augmenting intrinsic impedance, especially friction. The perceived actuator static friction<sup>†</sup> increases by the reduction ratio, and the viscous friction<sup>§</sup> by the square of the reduction ratio. To illustrate, by employing a gear reduction 200:1 to reduce actuator weight, we increase the perceived static friction by 200 and the viscous friction by 40,000. Therefore the resulting robot is likely to have an intrinsically high impedance; that is, if the robot is in the “off” state, it requires very high force to move it. Conversely, an end-effector, direct-drive robot that can employ larger actuators which are fixed at the base and are not mounted on the robot arms, has very low intrinsic and end-point friction and can easily be moved. The resulting robot is likely an intrinsically low impedance robot (e.g., MIT-Manus).

For an interactive experience, the robot must allow even weak patients to express movement and the two distinct designs require very distinct control strategies to achieve this goal. An intrinsically high impedance robot must employ an

aggressive control strategy to modify its behavior and reduce its inherent impedance to allow patients to express movement, no matter how weak. An intrinsically low impedance robot allows even weak patients to express movement, and simple control strategies can be employed to increase the robot's inherent impedance whenever therapy requires guided or restricted movement. It is important to note that in practice, intrinsically high impedance robots suffer from a significant limitation: we cannot arbitrarily increase the gains of the controller to reduce the perceived impedance. Eventually, the robot stability, and therefore safety, is compromised.

### Number of Degrees of Freedom

The optimum number of degrees of freedom is a difficult and critical question that requires considerable clinical insight supported by clinical results. The human body has many more degrees of freedom than any robotic device likely to be built. How many of those degrees of freedom should be actuated in a therapy robot? For instance, the human hand has 22 degrees of freedom and it is very unlikely that we will see any therapy robot in the near future that can interact in a controlled fashion with all of these degrees of freedom. This observation is valid for both upper and lower extremity. For the lower extremity, the ankle is a critical joint for gait. How many ankle degrees

<sup>†</sup>Friction is the force resisting relative movement between two objects. Static friction is the force between two objects not moving relative to each other. For example, static friction prevents a garbage can from sliding down a slope.

<sup>§</sup>Viscous friction is the force resisting movement which is proportional to the relative velocity of two objects or fluid layers.

of freedom do we need to actuate during gait rehabilitation? These questions can only be answered via exhaustive clinical trials based on a clinical understanding of the target user population. For example, MIT's new hand module was designed to train cylinder grasp (10). We opted for such an apparently limited design from our clinical understanding and experience with a previous eight degrees-of-freedom hand robot: the user of MIT robotic systems is likely a severe-to-moderate stroke patient with significant hemiparesis of the hand and fingers. For these patients, we simplified the mechatronic design considerably by limiting our goal and providing a tool to facilitate the training of *grasp*. We made a compromise to get a relatively low cost, light, and compact module that can easily be integrated with the shoulder-and-elbow MIT-Manus or wrist robots. Another case of design compromise is the Lokomat, designed to actuate the hip and knee in the sagittal plane but with no actuation at the ankle (11). Both robots embody reasonable compromises based on the best available expert insight at the time, but can we do better? Ultimately, all these designs must undertake rigorous and exhaustive clinical trials to determine their adequacy. This is a critical aspect that clinicians must demand and technology developers cannot ignore and must be prepared to undertake. This critical requirement makes the deployment of rehabilitation robotics the antithesis of rapid-fire demonstrations observed in many other technology arenas. Therapy robots and control algorithms must pass through a set of painstaking exhaustive clinical trials to determine, as noted previously, what works, what does not, what works better, when to apply the robotic tools and under what protocol, and for whom.

## CLINICAL RESULTS

### Upper Extremity Rehabilitation and Stroke

As discussed earlier, the biggest hurdle faced in therapeutic robotics is not the technology *per se* but its clinical validation. But every challenge is also an opportunity: robots provide an ideal platform for objective, reproducible continuous measurement and control of therapy. For a glimpse at the clinical results, meta-analyses are an outstanding source for an overall picture and comparison basis; there are at least three recently published articles that include a range of devices with more to come (4–8). Herein, we will summarize some of our results for the shoulder-and-elbow transport of the arm collected during a long series of clinical experiments involving well over 400 participants. We will then conclude reviewing the main findings of two meta-analyses. We will not include in this chapter a discussion of results with upper extremity distal robots (12).

### Subacute Rehabilitation

Volpe et al. reported the composite results of robotic therapy with 96 consecutive stroke inpatients admitted to Burke Rehabilitation Hospital in White Plains, NY (13). These patients were on average 2 weeks after an acute first stroke. All participants received conventional neurological rehabilitation

during their participation in the study. The goal of the trial was to amass initial evidence to test whether robotic therapy had a measurable impact on recovery. Hence, we provided one group of patients with as much therapy as possible to address a fundamental question: does goal-oriented movement therapy have a positive effect on neuromotor recovery after stroke?

Patients were randomly assigned to either an experimental (robot-trained) or control (robot-exposure) group. Individuals in the robot-trained group were seen for five 1-hour sessions each week and participated in 25 sessions of sensorimotor robotic therapy for the paretic arm. Patients were asked to perform goal-directed, planar reaching tasks that emphasized shoulder and elbow movements with their paretic arm. MIT-MANUS' low impedance guaranteed that the robot would not suppress any attempts to move. When a patient could not move or could not be deviated from the desired path or was unable to reach the target, the robot provided soft guidance and assistance dictated by an impedance controller (14). This robot action (which we dubbed "sensorimotor" therapy) was similar to the "hand-over-hand" assistance that a therapist often provides during conventional therapy. It is interesting to note that this form of "assistance as needed," which has been a central feature of our approach from the outset (and a challenge for our robot designs), has recently been adopted and promoted by other groups (15,16).

Individuals assigned to the robot-exposure (control) group were asked to perform the same planar reaching tasks as the robot-therapy group for only 1 hour per week. However, the robot did not actively assist the patient's movement attempts. When the subject was unable to reach toward a target, he or she could assist with the unimpaired arm or the technician in attendance could help complete the movement. The robot supported the weight of the limb while offering negligible impedance to motion. For this control group, the task, the visual display, the audio environment (e.g., noise from the motor amplifiers), and the therapy context (e.g., the novelty of a technology-based treatment) were all the same as for the experimental group, so this served as a form of "placebo" of robotic movement therapy.

The study was "double blinded" in that patients were not informed of their group assignment and therapists who evaluated their motor status did not know to which group patients belonged. Standard clinical evaluations included (a) the MRC motor power score for four shoulder and elbow movements (MP; maximum score = 20) and (b) the motor status score which is divided into two subscales, one for shoulder and elbow movements (MS-SE, maximum score = 40) and a second for wrist and hand abilities (MS-WH, maximum score = 42) (17–20). The MS-SE and MS-WH have met standards for interrater reliability, significant intraclass correlation coefficients, and internal item consistency for inpatients (21).

Although the robot-exposure (control) and robot-treated (experimental) groups were comparable at admission, based on sensory and motor evaluation, on clinical and demographic scales, and the fact that both groups were inpatients in the same

**TABLE 83.1** Burke Inpatient Studies ( $N = 96$ ) Mean Interval Change in Impairment and Disability (Significance  $p < 0.05$ )

Between Group Comparisons: Final Evaluation Minus Initial Evaluation	Robot Trained ( $N = 55$ )	Control ( $N = 41$ )	$p$ -Value
Impairment measures ( $\pm$ SEM)			
Fugl-Meyer shoulder/elbow (FM-SE)	$6.7 \pm 1.0$	$4.5 \pm 0.7$	NS
Motor power (MP)	$4.1 \pm 0.4$	$2.2 \pm 0.3$	$<0.01$
Motor status shoulder/elbow (MS-SE)	$8.6 \pm 0.8$	$3.8 \pm 0.5$	$<0.01$
Motor status wrist/hand (MS/WH)	$4.1 \pm 1.1$	$2.6 \pm 0.8$	NS
Disability evaluation			
Functional independence measure (FIM)	$32.0 \pm 5.0$	$25.5 \pm 6.5$	NS

stroke recovery unit and received the same standard care and therapy for comparable lengths of stay, the robot-trained group demonstrated significantly greater motor improvement (higher mean interval change  $\pm$  SEM) than the control group on the MS-S/E and MP scores (Table 83-1). In fact, the robot-trained group improved twice as much as the control group by these measures. Notably, these gains were specific to motions of the shoulder and elbow, the focus of the robot therapy. There were no significant between-group differences in the mean change scores for wrist and hand function.

Our initial result supported our working model indicating that, to promote recovery, we need to harness the correct sequence of events much like the Hebbian rule for neural plasticity, which is colloquially summarized as “neurons that fire together wire together.” We believe that, in order to promote maximum recovery, events must occur in a proper sequence: the target is displayed, the patient attempts to move, movement then happens (either self-generated or assisted by the robot), and the sensory information comes back to the brain. Though this was a modest beginning, it provided unequivocal evidence that robotic therapy of the kind that might be delivered by a robot had a significant positive impact on recovery.

### Follow-up

We were able to recall 31 of these 96 patients 3 years after discharge from the subacute hospital. The goal was to determine if the advantage conferred on the robot-trained group over the control group was sustained. It is possible that the short-term additional gains of the subacute phase were temporary and that, ultimately, patients in both the experimental and control groups would achieve the same clinical “plateau.” Such a result is of interest as it would suggest that robot-mediated therapy might contribute to the acceleration of recovery but not to the ultimate outcome. Figure 83-3 shows the motor power for these 31 patients. Results from this follow-up study demonstrated that the robot-mediated group maintained the advantage over the control group. Furthermore, we observed that both groups improved significantly from discharge of the subacute hospital to the 3-year follow-up. While we did not control any intervention during this period, this result showed

further impairment reduction. Such a result is quite important because it contradicts epidemiological studies which suggested that, after 12 weeks poststroke onset, there is little opportunity for further impairment reduction (22,23). It also demonstrates that the clinical “plateau” has little support from biology and there is an opportunity to impact recovery in persons with chronic impairment due to stroke, perhaps many years after the injury.

Bolstered by this result showing the positive and measurable impact of robotic therapy on neurorecovery, we are systematically investigating the multitude of variables that may influence outcome to determine their independence, their interaction, and their actual impact on outcomes in acute, subacute, and chronic phases of stroke. Our goal is the “holy grail” of robotic therapy, to determine how best to customize the treatment protocol to meet each individual patient’s needs.

Mean  $\pm$  standard error Motor Power scores (maximum score 20) of 96 patients on admission before rehabilitation, at discharge after rehabilitation and robotic training or control, and at follow-up evaluation approximately 3 years after stroke. Robot-trained patients maintain the motor improvements. \* $P < 0.05$ , versus control.

**FIGURE 83-3.** Change in motor power in patients recovering from stroke.

### Continuous Passive Motion

Kwakkel has shown that a task-oriented training of high intensity is perhaps the most important aspect of a comprehensive stroke rehabilitation program (24). Volpe et al. tested whether intensity alone would suffice (25). To that end, they recruited subacute patients at the Burke Rehabilitation Hospital, White Plains, NY, and compared 25 minutes of additional conventional therapy with 25 minutes employing a CPM device (Continuous Passive Motion—Shoulder 600, Orthologic, Tempe, AZ), while patients' attention was held by TV or social conversation. A CPM machine is an intrinsically high impedance device that employs position control and moves the patient's shoulder or elbow passively. Patients cannot freely express any movement. Of note, there was no neurological advantage conferred on the CPM group. Patients in both groups showed comparable improvement in the neurological scales. This result reinforced our Hebbian view that, in order to improve outcomes, therapy must elicit the proper sequence of events and patients must participate actively and attempt to move. It is important to mention that while no neurological benefit was observed, the CPM group exhibited an apparent benefit in terms of shoulder stability and none of the patients in this group developed pain. Therefore, it became standard of care at Burke Rehabilitation Hospital to assign any stroke patient starting to show signs of shoulder pain to a daily session of movement therapy administered via the CPM machine.

### Intensity-Matched Rehabilitation

The neurorehabilitation process is labor intensive, relying on therapy and evaluation procedures that are typically administered by a clinician working with a single patient. This one-on-one interaction characterizes much of the practice of clinical neurology. The repetitive nature of therapy makes it amenable to administration by properly designed robots. A robotic therapist can act as a modern, effective and novel tool, one that delivers a highly reproducible motor learning experience, quantitatively monitors and adapts to patients' progress, and ensures consistency in planning a therapy program. Indeed, our research suggests that robotics can afford a much more intense experience than traditional therapy. For example, Kahn et al. noted that in a typical conventional therapy session, patients attempt to move their impaired arm circa 60 to 80 times (27). In a typical robot-mediated therapy session, patients must attempt to move 1,024 times. To confirm the importance of task-oriented training and intensity, we conducted a clinical trial including three groups of stroke patients: usual-care, robot-mediated therapy, and human-administered intensive-matched therapy. The last group was an attempt to match human-administered therapy and the intensity of typical robot-mediated sensorimotor therapy (1,024 attempts to move in each session). Though this latter form was somewhat artificial and impractical, results demonstrated that there were no significant differences in outcomes between robot-mediated and human-administered intensive-matched therapy groups; furthermore both groups improved far more than the

usual-care group (28). These results further support Kwakkel's assertion of the importance of a comprehensive rehabilitation program encompassing task-oriented movements of high intensity (24).

### Motor Learning as a Model for Motor Recovery\*\*

Given the apparent importance of high intensity and a patient's active participation in therapy, we revised our robot control algorithm to test whether continuously challenging a patient would enhance recovery. The revised algorithm differs from our earlier sensorimotor therapy in three important ways (29).

First, during our earlier clinical trials, robotic therapy took the form of fixed, repetitive reaching exercises cued by a video display. An impedance controller with constant stiffness and damping made the therapy interactive: the force exerted by the robot varied continuously as a function of the deviation of the patient's motion from a minimum-jerk trajectory of constant duration that connected the start position to the goal position. This system suited patients with limited motor ability for whom it provided assistance; however, it would also impede patients who moved faster than the nominal trajectory. Our revised algorithm used nonlinear impedance control to implement a "virtual slot" that extended between the start and goal positions and defined the appropriate coordination. Lateral deviation from the desired path was discouraged by the stiffness and damping of the slot sidewalls. Desired motion was assisted by moving the back wall of the slot along a minimum-jerk virtual trajectory so that the slot progressively "collapsed" to a "virtual spring" centered on the goal position. However, motion along the "virtual slot" (well aimed and faster than the nominal desired trajectory) was unimpeded.

A request for the subject to move was signaled by a target in the visual display changing color. If the patient failed to initiate movement within 2 seconds, the robot began to act (i.e., the back wall of the "virtual slot" closed on the goal position). This mode of triggering the robot encouraged even severely impaired patients to participate actively, rather than passively allowing the robot to drive the arm.

Second, the revised algorithm continuously monitored the patient's performance. By combining records of the kinematics of actual patient motion and the kinetics of mechanical interaction between robot and patient, five performance measures (PMs) were computed: PM1 graded patients' ability to initiate movement, PM2 measured movement range or extent, PM3 measured the power delivered by the patient to complete the movement, PM4 measured the smoothness of the movement, and PM5 measured aim or deviation from the straight line connecting the center and outbound target. We used these measures to adjust the parameters of the controller during a therapy session. For the first five cycles of movements to the eight goal positions and back to the center position, the time allotted for a movement (the duration of the nominal minimum-jerk trajectory) and the stiffness (impedance) of the

\*\*Parts of this section are similar to (30).

“virtual slot” sidewalls were adjusted approximately to match the patient’s current performance and need for guidance. This was important because patient performance typically declined between the end of one therapy session and the beginning of the next. For every subsequent five cycles of reaches to and from the eight goal positions, the controller parameters were adjusted based on the patient’s performance. The intent was to challenge the patient to improve.

As patients aimed better, the stiffness of the “virtual slot” sidewalls was decreased (and vice versa). As patients moved faster, the time allotted for movement was decreased (and vice versa). Again, this was intended to encourage active participation of even the most impaired patients, yet continuously challenge patients as they recovered.

Third, to provide motivation, positive reinforcement, and knowledge of results, our revised algorithm provided specific, movement-related feedback in the form of a simple graphical display that consisted of five vertical bars to reflect recent patient performance. The height of each of the five bars was determined by the five PMs, expressed as a percentage.

This performance-based progressive therapy (PBPT) algorithm provided support for patients to progress from complete plegia to normal arm movement. PM1, which measured ability to initiate movement, was probably most important for severely impaired patients and helped to ensure appropriate timing of afferent and efferent signals, which may be important for reestablishing the excitability of corticospinal projections (13,31–34). PM2 measured active ROM, an important clinical measure of function, and also rewarded hypertonic patients for relaxing their arms, which allowed the impedance controller to move their hands closer to the target. PM3 measured active power delivered by the patients, probably important for less severe patients that could reach most but not all targets. PM4 and PM5, which respectively measured movement smoothness and the aim or deviation from the straight line connecting the center to the outbound target, quantified the trade-off between speed and accuracy that is characteristic of unimpaired movement and was probably most important for patients with mild-to-moderate impairment.

The PBPT protocol was evaluated by a clinical study of 28 chronic stroke patients between the ages of 39 and 81 with chronic motor impairment following a single stroke that had

occurred between 8 and 95 months before the initial assessment (35). All patients were evaluated six times: three times in a 2-month period before the start of therapy to assess baseline performance, at the midpoint and discharge from robotic therapy (18 one-hour sessions of robotic training, three times a week for 6 weeks), and finally at a follow-up evaluation session 3 months after robotic training. Evaluating therapists were different from treating therapists (Table 83.2).

The first three evaluations showed no significant changes on any of the impairment scales, which verified that subjects were indeed at the chronic phase of their recovery. Subsequent evaluations showed that the PBPT protocol evoked a statistically significant improvement in motor performance that was maintained at the 3-month follow-up. This result confirms earlier studies of chronic-phase patients (36–38) and shows that amelioration of chronic neurological impairments long after the expected period for recovery following stroke is possible. More important for our understanding of recovery, the magnitude of the improvement achieved with PBPT was many times greater than that achieved with our previous robotic therapy. Of course, a large randomized clinical trial (RCT) must follow to confirm this finding. Nevertheless, it is worth stressing that the only change was the therapy protocol: the same robot assisted with the same set of reaching movements. A treatment protocol that adapted to the patient’s motor ability and presented a continuous challenge substantially enhanced recovery.

### Meta-Analysis

While the gold standard in clinical research is the RCT, meta-analysis compiles results from multiple groups and affords a map of the land. Here we summarize two meta-analyses (7,8) (Fig. 83-4).

Prange et al. conducted a systematic review of the literature between 1975 and August 2005 (7). They identified articles on the use of different robots to deliver therapy to stroke patients including MIT-Manus, Assisted Rehabilitation and Measurement (ARM) Guide, Mirror Image Motion Enabler (MIME), Bi-Manu-Track, Gentle/s, Neurorehabilitation Robot (NeReBot), REHAROB, Arm Coordination Training 3D (ACT), ARMin, Exercise Machine for Upper Limbs (EMUL), Rutgers Master II (RMII), and Mechatronics system for Motor recovery after Stroke (MEMOS). They identified

**TABLE 83.2** Motor Impairment Outcomes of Performance-Based Progressive Robotic Therapy

**FIGURE 83-4.** Meta-analysis of robot-assisted therapy trials on motor recovery (From Kwakkel G, Kollen BJ, Krebs HI. Effects of robot-assisted therapy on upper limb recovery after stroke: a systematic review. *Neurorehabil Neural Repair*. 2008;22(2):111–121.), with permission.

17 clinical trials, of which only 4 ultimately were included in the final analysis. These studies involved three robots: MIT-Manus, MIME, and Arm Guide; with an aggregate of 178 experimental subjects and 50 control subjects. Prange et al. concluded that “robot-aided therapy of the proximal upper limb can improve short- and long-term motor control of the paretic shoulder and elbow. This conclusion is supported by a quantitative analysis of short-term pooled FM data in chronic stroke patients and indicates that increased motor recovery of chronic patients is possible after robot-aided therapy. However, no consistent effect on the improvement in functional abilities has been reported. Restoration of motor control appears greater after robot-aided therapy than conventional therapy. We could not establish which aspects of robot-aided therapy (e.g., increased intensity of movements, most effective training modalities) were most responsible for the beneficial influence on recovery. The clinical relevance of our findings is that robot-aided therapy is a promising new approach to rehabilitation of upper-limb motor control after stroke. For both subacute and chronic stroke patients, robot-aided therapy can improve motor control of the hemiparetic upper limb, perhaps even more than conventional therapy.”

Kwakkel included studies published by October 2006 (8). A computerized literature search was conducted in MEDLINE, CINAHL, EMBASE, Cochrane Controlled Trial Register, DARE, SciSearch, Doonline, and PEDro and it returned 173 hits. Contrary to Prange’s meta-analysis, Kwakkel et al. opted to include only papers that compared robot training against a control group. Excluded were many studies included in Prange’s meta-analysis that compared different forms of robotic therapy and studies on chronic stroke that compared

discharge values with admission values. Ultimately, ten studies involving 218 patients achieved methodological quality and were included in further analysis. These studies involved four devices: MIT-Manus, MIME, Bi-Manu-Track, and Arm Guide. Analysis of the entire set indicated nonsignificant effect, possibly due to heterogeneity. Kwakkel et al. eliminated the outliers in further analysis (Kahn 2001; Hesse 2005) and concluded that “sensitivity analysis showed a significant improvement in upper limb motor function after stroke for upper arm robotics. No significant improvement was found in ADL function. However, the administered ADL scales in the reviewed studies fail to adequately reflect recovery of the paretic upper limb.”

### Gait Rehabilitation and Stroke

Restoration of gait is a major aspect of stroke rehabilitation. Three months after stroke, 25% of surviving subjects remain wheelchair-dependent and in 50%, gait speed and endurance are considerably reduced (39). Traditional treatment concepts in Europe put emphasis on tone-inhibiting and gait preparatory maneuvers, assuming a transfer of skill acquisition from one motor task to the other. Gait itself is practiced very little, rarely more than 50 to 100 steps per session. Not surprisingly, a large outcome study failed to show a relevant improvement of gait function and symmetry in 160 ambulatory subjects following 4 weeks of Bobath treatment (40). Modern concepts of motor learning favor a task-specific, repetitive approach, which for gait, we translate into “who wants to regain walking has to walk.”

Treadmill training with partial body weight support was introduced in the early 90s to intensify gait practice (41,43).

It employed a harness not only to support patients with poor balance but also to unload the paretic leg, while the treadmill enforced locomotion. The repetitive nature of gait therapy makes it amenable to administration by properly designed robots. Such robots relieve the strenuous repetitive effort of therapists during gait rehabilitation of wheelchair-dependent subjects on a treadmill. Although various robot-mediated gait training devices are available, the limited number of clinical studies have largely used the Lokomat (Hocoma, Zurich, Switzerland) and Gait Trainer I (GT I, Reha-Stim, Berlin, Germany).

The Lokomat combines a motorized, body-weight supported treadmill (BWST) with a robot-driven gait orthotic (44). During training, lower extremity movements are controlled at the hip and knee, while the pelvis and thorax are stabilized. If necessary, the foot is dorsiflexed with lifter straps to prevent the forefoot or toe box of the shoe from catching, should foot drop be present. The robot-driven hip and knee movements are synchronized with the treadmill. A number of gait variables can be regulated. The primary variables are body-weight support (0% to 100%) and treadmill speed (0 to 3.2 km/h). The range of motion at the hip and knee can be increased or decreased, and the trunk can be positioned in slight flexion or extension. These adjustments enable fine-tuning of subtle issues such as toe clearance, stride length, or heel strike placement in transitioning from swing to stance phase.

The GT I applies the principle of movable footplates, where each of the patient's feet is positioned on a separate footplate whose movements are controlled by a planetary gear system, simulating foot motion during stance and swing (45). Cadence and stride length can be tailored to the individual patient's need. The vertical and horizontal movements of the center of mass are controlled via ropes attached to the harness. The device affords

bilateral and distal guided gait training. Patients' knees are not fixed. Therapists have easy access to patients which allows minor corrections of the knee motion if needed. Contrary to the Lokomat, the GT I imposes minimum number of constraints on natural hip and leg motion. Tight attachment of the leg to a robot with a technically limited number of degrees of freedom results in a more constrained leg motion.

Following are some results on stroke recovery with the electromechanical GT I, shown in Figure 83-5 and the Lokomat.

### Deutsche GAngtrainer Studie

Four centers recruited 150 (155) nonambulatory first-time stroke patients, who could sit and hold the trunk straight at the edge of the bed for 5 minutes and had no severe arthritis or contractures. Patients were randomly assigned to two groups. Group A received 20 minutes GT I plus 25 minutes of standard physiotherapy (PT) while group B received 45 minutes of standard PT. Therapy was administered daily except during weekends and lasted for 4 weeks. Responders were those patients who were able to walk (Functional Ambulation Category (FAC) 4 or 5) or who reached a Barthel Index (BI) of at least 75 (45).

At the end of the treatment, significantly more patients in group A had become responders: 41 versus 17 with respect to FAC ( $p < 0.0001$ , Fig. 83-6) and 44 versus 21 with respect to the BI 75 ( $p < 0.0001$ ). At the 6-month follow-up, the superior gait ability persisted (54 vs. 28,  $p < 0.0001$ ), while the BI responder rate did not differ. For all secondary variables, including gait velocity and gait endurance, the experimental group had improved significantly more ( $p < 0.0001$ ) during the treatment period but not at follow-up. For a subgroup of patients ( $N = 60$ ), heart rate intensity was recorded during the training with patients in group

FIGURE 83-5. Electromechanical Gait Trainer GT I.

FIGURE 83-6. Box plot of the Functional Ambulation Category (0–5, 0 = unable to walk, 5 = able to walk independently including stair climbing) of the experimental (GT I + physiotherapy) and of the conventional (physiotherapy) group at study onset, at end of intervention, and at follow-up.

A exercising longer at the target zone heart rate than patients in group B (16.1 vs. 5.3 min,  $p < 0.001$ ; (46)).

While DEutsche GAngtrainer Studie (DEGAS) is presently the largest RCT on robot-assisted gait rehabilitation, there are other randomized trials using the GT I (47,48). Studies with the Lokomat and stroke involved smaller sample sizes, with the largest study involving forty eight (50) chronic stroke survivors receiving 12 sessions of 30 minutes of either Lokomat training or therapist-assisted training at similar speeds (49). The results favored the therapist-assisted training over robotic training particularly for the less severe survivors. While more studies are needed, this study clearly exemplifies the importance of corroborating clinical evidence and of the understanding of the different variables that might influence outcome and that in most cases can be controlled via software modification.

The most up-to-date review and meta-analysis of the clinical results employing robotic-assisted gait training on stroke, including the GT I and Lokomat (Hocoma), are included in a recent Cochrane review. Mehrholz pooled all available data, including abstracts, and concluded that patients who receive electromechanical-assisted gait training in combination with PT after stroke are more likely to achieve independent walking than patients receiving gait training without these devices (9). Besides the GT I and Lokomat, Mehrholz considered the UC Irvine's PAM-POGO, MIT's Anklebot, and the Autoambulator (Healthsouth) among others, but these devices presently lack the clinical results to substantiate their use (50).

### Gait Rehabilitation and Multiple Sclerosis

We have described application of robot-mediated therapy in persons with upper and lower impairments due to stroke, but the potential of this technology is not limited to stroke. Here, we describe initial results on the use of the technology to gait rehabilitation in multiple sclerosis (MS), but there are other applications of the robotic technology in spinal cord injury, cerebral palsy, traumatic brain injury, Parkinson's disease, postsurgical rehabilitation following orthopedic trauma, etc. In MS, our evolving understanding of the disease process, particularly pathophysiology as it relates to physical activity, has translated into the development of new training protocols.

MS differs from stroke in a number of ways, including disease characteristics and sites of neurological injury. These differences in pathophysiology, etiology, site of injury, chronicity, and variable course can lead to additional treatment challenges for MS. MS is both an autoimmune inflammatory process as well as a disease process involving the loss of neurons and axons along the central nervous system (CNS) (51). In MS, neurological sites of pathology are widespread and multifocal and include the white matter tracts, the gray matter of the cerebral hemispheres, the subcortical structures, the cerebellum, and the spinal cord. In addition to primary motor, sensory and cerebellar deficits, fatigue is a very prevalent and prominent issue that can limit physical activity (52,53). The disease process for MS is not time restricted; rather, MS is an active disease, generating ongoing acute and chronic neurological impairments. The

clinical course for MS is characterized by relapses and remissions superimposed over progressive disability.

In the past, because of the ongoing inflammatory process in MS, there was the fear of possibly triggering an exacerbation, and clinicians have historically been cautious in recommending exercise (54). Nevertheless, this concern has not been substantiated by the literature on exercise and rehabilitation (55), and presently, the general recommendation is that persons with MS should participate in exercise and physical activity. This recent shift in exercise philosophy has been accompanied by growing interest in pursuing rehabilitation studies for MS. Since disability in MS accumulates over a period of time, there is an opportunity for early intervention to alter the natural course of functional decline.

Although various robot-mediated gait training devices are available, the limited number of studies conducted in MS populations has largely used the Lokomat (Hocoma, Zurich, Switzerland).

Beer et al. recently published the results of an RCT comparing Lokomat robot-assisted gait training to conventional walking training in MS patients with Kurtzke Expanded Disability Status Scale (EDSS) scores ranging from 6.0 to 7.5 (56). The protocol consisted of daily 30-minute sessions of either robot-assisted training ( $N_1 = 19$ ) or conventional training ( $N_2 = 16$ ) for a total of 15 sessions. Gait training of either type was supplemented with 16 hours per week of general physical therapy or occupational therapy. Primary study outcomes included walking velocity (20 m walk), 6-minute walk (6 MW), stride length, and knee extension strength. Results showed that both groups improved on walking velocity (28% and 29% for robot-assisted and conventional training group, respectively), whereas the robot-assisted training group improved slightly more on distance (9.5% compared to 4.5% for the conventional training group) (Table 83-2).

In another study, one of us conducted a crossover study, comparing robot-assisted gait training with BWST training in 13 subjects with either relapsing-remitting or primary progressive MS (EDSS  $4.9 \pm 1.2$ ) (55). Subjects received a total of twelve 45-minute training sessions, either starting with BWST alone or BWST with robotic assistance, and then crossing over to the alternative intervention. Gait outcomes included the timed 25-foot walk (T25FW), 6MW, EDSS, double support time (DST), and step length ratio (SLR). At midpoint (prior to crossing over), median percent changes for gait outcomes were actually greater for the treadmill alone group compared to the treadmill with robot-assisted group for T25FW (37.6% vs. 15.9%) and DST (-5.9% vs. -1.9%), whereas robot-assisted group had slightly greater change for 6MW (22% vs. 19%) and SLR (2.0% vs. 0.4%). However, none of these differences achieved statistical significance.

These pilot studies show that robot-assisted rehabilitation is feasible and safe in the MS population. While these pilot studies did not demonstrate therapeutic advantages of robot-assisted therapies over more conventional therapies such as treadmill training, the labor-intensive nature of the latter confers a significant advantage to the employment of robot-mediated therapy.

## DISCUSSION

### Neurological Considerations for Motor Neurorecovery

After a brain injury, the neurophysiology that underlies recovery depends on the flexibility of remaining neurons and the altered synapses in the multiple circuits to reorganize the sensory motor processing that had developed over a lifetime. Nineteenth-century neuroscientists thought about recovery using concepts like “diaschisis”—resolution of the depression of functionally connected but anatomically distant circuits, so that recovery required the unmasking of functionally inactive connections. Another consideration of recovery was called “vicariation”—a particular brain circuitry that had been dedicated before the injury to contributing an aspect of sensory motor function and which might, after the injury, contribute to the control of a new function. In the 20th century, imaging and detailed electrophysiological data supported these ideas (58–60). In the 21st century, the promise of recovery has moved into the molecular age and it appears more to depend on learning mechanisms that may in turn be influenced by task-specific intensive human/machine interactions (29), the effect of transcranial direct current (61–63) or magnetic stimulation (63–65), the potential of persistent neurogenesis (66,67), the possibilities of transplantation of neurons or viral factories for the production of transmitters, growth and transcription factors, and a variety of other signaling molecules that amplify the learning conditions (68). As a result, recovery can be revised by operationally testable terms like reorganize, as in train networks that underlie behaviors (69–71); replenish, as in increase depleted dendritic fields and their synaptic spines (72); replace, as in transplant cellular or molecular slurries of neurons and glia or deliver molecules that abet the formation of new connections (73,74), support or repair damaged connections (75–77). All of these modern mechanisms play a role in recovery after neurological injury.

Neurological injury fills textbooks with its diversity. However, for the purpose of this discussion we restrict ourselves to stroke which plays out over minutes, hours, and days, but recovery processes play out over months, perhaps many months and years. Recovery depends on the severity (78), details of the location (79,80), and the type of injury and concurrent medical condition (81). Treatment for stroke also proceeds in stages that require multimodal programs. Stabilization of the crisis by clot dissolution or removal, vessel repair, or blood pressure control gives way to the beginning of recovery, decreasing the risk of a second event. Therapy for recovery proceeds with general efforts to encourage the patient to move and to exercise in a wide array of training protocols and now with an equally broad array of devices. Because the currency of the coordinated activity of neurons is behavior, it is no surprise that there is much information about the effect of environment and, more particularly, the nurturing aspects of environment on the development of motor behavior. Early studies of the effect of an enriched environment on the developing nervous system inform current models of recovery that

have expanded to include task-specific training (82–84). It is this background that has led trained therapists into the sick room of the patient with stroke, first to passively move the paralyzed limbs and then actively guide the performance.

### Physiological Considerations for Motor Neurorecovery

Traditional therapies do not recognize the long-term detrimental effects of reduced mobility, deconditioning, and muscular wasting. Investigators have long recognized that energy demands of paretic gait are 1.5- to 2-fold higher. It has also been shown that a mean  $\text{VO}_2$  of 10 mL/kg/min is required to maintain slow walking effort. Yet, Macko et al. have shown in a large cohort of persons with chronic stroke that their peak  $\text{VO}_2$  was just 13.8 mL/kg/min, which is 50% lower than sedentary age-matched healthy individuals; it indicates a  $\text{VO}_2$  consumption of 70% of their peak capacity just to walk very slowly (85). This finding reveals a detrimental combination of poor fitness and energy inefficient gait potentially leading to immobility. Hence, the rationale for exercise to improve fitness even without neurological improvement is solid.

Fitness programs might include many modalities including robotic training. As described earlier, for a subgroup of 60 patients of the DEGAS study, the heart rate intensity during training with the robotic-assistant was higher than for patients receiving standard therapy (45). Furthermore, robotic devices can be used in many fashions including resistive exercises, which might be even more beneficial from the fitness viewpoint. It is important to note that older literature on exercise therapy for individuals with conditions resulting in “upper motor neuron” neurological damage (principally stroke, traumatic brain injury, spinal cord injury, MS, and cerebral palsy) raised theoretical concerns about causing increases in abnormal muscle tone, especially with resistive exercises (86). More recently, several studies have been conducted to clarify the impact of resistance training on spasticity and found that it has little effect (87–91).

While resistive exercises for the paretic limbs appear safe after stroke and might improve fitness, their impact on neurorecovery remains uncertain. Studies of strength training have not found improved motor control or function in the upper limbs (92–94), but have found modest benefit in the lower limbs (87–91).

Robotic studies of the MIT-Manus/InMotion2 robot also reveal the same stereotypical pattern of flaccidity followed by increase in tone and spasticity for subacute patients (17), but interestingly, both for subacute as well as for chronic strokes, robot training appears to have no impact on tone and spasticity when compared against standard therapy. In fact, there is a trend toward reduced spasticity (35–37), with the incorporation of resistance training into robotic therapy having no measurable impact (38). A study of children with hemiplegia from cerebral palsy employing the same device found small but statistically significant reductions in spasticity. This occurred primarily at the elbow after a course of training with the InMotion2 robot (95). Likewise, a pilot study of an EMG-controlled powered elbow brace found significant reductions in spasticity at the elbow (96).

Similar results were observed for the lower extremity. Individuals with spinal cord injury undergoing an 8-week training program with the Lokomat found no change in the Ashworth scale, though reductions in extensor spasms were seen on the Spinal Cord Assessment Tools for Spasticity scale (97).

In summary, there is a strong evidence-based consensus recommending regular exercise to improve fitness and cardiovascular health for all ages and that it is even more acute for persons with chronic disability. This recommendation can be implemented employing many modalities, including robots programmed to challenge cardiovascular fitness. In fact, it appears that robot-assisted exercise may have a modest but measurably positive effect on spasticity, with the exact mechanism(s) yet to be fully elucidated. The effects observed to date have been primarily in the limb segments exercised, rather than in other upper-limb segments, suggesting that the effect is related to the performance of robot-assisted exercise rather than a physiological change, nonspecific effect of observation or measurement.

### Neuroscience Considerations of Motor Neurorecovery

Since the evidence supporting the benefits of a cardiovascular fitness programs is unequivocal, should robotic training optimize cardiovascular fitness? Common sequelae of neurological injury include spasticity, abnormal tone, disrupted or unbalanced sensory pathways, and muscular weakness. These deficits appear to involve the peripheral nervous system and might suggest that muscles should be the focus of therapy.

Should robotic training optimize muscle strength? The answer is likely more complex, and there is a significant body of evidence supporting an alternate assumption that robot-mediated therapy can also help patients “relearn” motor control. Though intuitively sensible, this notion may need to be refined, as normal motor learning does not have to contend with the neuromuscular abnormalities already discussed. Our results for upper extremity show that, although the process of recovery may share some features of motor learning (such as specificity), the relationship between learning and recovery may be subtle. While movement is beneficial, movement alone is not sufficient. Active involvement of the patient is important. Despite the fact that repetition may be beneficial, repetition alone is not sufficient; the benefits of robotic therapy do not exclusively derive from the high “dosage” of movement delivered. Our working model suggests that, in order to promote recovery, we need to include all of the above elements presented in a proper sequence of events.
